## PREFACE

THE problems with which an active statistical department may have to deal require, if their solutions are to be made widely accessible, a great variety of special tables. A number of those in the present book are familiar to statisticians, and are already widely used. In presenting them in a convenient form, the opportunity has been taken to supplement them with a selection of others, chosen as likely also to be of value, and not accessible elsewhere. The volume is completed with a number of tables of standard functions of general utility. The experience of the authors of the problems arising in practical research, is the basis of the selection, from among those tables which from time to time have been computed for special purposes.

To perform their compilation, the main work has been to complete the tables in a form suitable for the general user, and, what is by no means easy, to ensure their entire accuracy. In addition we have been principally concerned with the design of printing and arrangement, which shall be suitable both for constant and for occasional users. Comments from both classes of reader will therefore be especially valued.

We are indebted to all workers at the Galton Laboratory, and at the Statistical Laboratory, Rothamsted, and especially to W. L. Stevens, for assistance in the completion of our task.

## PREFACE TO SECOND EDITION

THE second edition contains as new material Tables V<sub>1</sub> and V<sub>2</sub> for the test of significance of the differences between two means obtained by different methods; Table VIII<sub>1</sub>, which supplies solutions of the type of problem illustrated in Examples 1, 2 and 4, more direct than those previously available; and Table VIII<sub>2</sub>, which gives densities of organisms estimated by the dilution method.

The combinatorial solutions of Table XVII have been considerably extended and simplified in presentation by the more extensive use of solutions of the cyclic type. The corresponding section of the introduction now gives an account of Youden's Squares, and of the

## PREFACE

method of utilising information, formerly discarded, from comparisons between blocks.

For the convenience of owners of the first edition, a list of errata has been included showing all the errors of any importance that have been discovered in the first edition. Our thanks are due to those who have drawn our attention to these errors.

# INTRODUCTION

## TABLES I TO VII. TESTS OF SIGNIFICANCE BASED ON THE NORMAL DISTRIBUTION

Tables I to VII constitute a group of tables, based on the normal distribution, and now widely used in making tests of significance. The common uses of these tables are fully illustrated with numerical examples in Fisher's *Statistical Methods for Research Workers*, where they were first published. Further statistical problems soluble by the same tables are, however, constantly being discovered.

If  $x$  is the deviation from the mean of a normal distribution having unit variance, the ordinate  $z$ , given in Table II, is obtained from the algebraic expression

$$z = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}x^2}$$

The integral of this function gives the area of the curve, or the frequency of observations, between the limits of integration. The fraction of the frequency falling outside the limits  $\pm x$  is, therefore,

$$P = 2 \int_x^\infty z dx$$

Table I gives the values of  $x$  corresponding with various values of this fraction.

The distribution of  $t$ , due originally to "Student," is used to test the significance of a deviation when its standard error is *estimated from the data*;  $t$  is the deviation divided by its estimated standard error. The algebraic expression for the ordinate of the distribution is

$$\frac{\frac{n-1}{2}!}{\frac{n-2}{2}! \sqrt{\pi n}} \cdot \frac{1}{\left(1 + \frac{t^2}{n}\right)^{\frac{1}{2}(n+1)}}$$

Table III gives the values of  $t$  corresponding with various values of the probability of a random value falling outside the limits  $\pm t$ . The integer  $n$  is the number of degrees of freedom available for the estimation of error.

The quantity  $x^2$ , used to test goodness of fit, homogeneity, and for a variety of other purposes, may be regarded as the sum of the squares of  $n$  variables, which vary normally and independently about zero with unit variance. It is a useful single measure of the aggregate of a set of deviations from expectation. The element of frequency may be expressed as

$$df = \frac{1}{\frac{n-2}{2}!} (\frac{1}{2}x^2)^{\frac{1}{2}(n-2)} e^{-\frac{1}{2}x^2} d(\frac{1}{2}x^2)$$

When  $n$  is even the probability of exceeding any given value  $x^2$  is reducible to the partial sum of a Poisson series:

$$P = \int_{x^2}^\infty df = e^{-\frac{1}{2}x^2} \left\{ 1 + (\frac{1}{2}x^2) + \frac{1}{2!} (\frac{1}{2}x^2)^2 + \dots + \frac{1}{\frac{n-2}{2}!} (\frac{1}{2}x^2)^{\frac{1}{2}(n-2)} \right\}$$

The mean of the whole Poisson series is  $\frac{1}{2}x^2$ , the sum of the whole series is unity, and the number of terms in the partial sum is  $\frac{1}{2}n$ . In consequence the table of  $x^2$  (Table IV), which gives the values of  $x^2$  for various values of  $P$ , can be used to find the mean of a Poisson series of which the first  $\frac{1}{2}n$  terms constitute a given fraction of the whole.

### *Example 1*

Four serious floods have occurred in a given region during a century's experience; supposing the numbers of floods experienced in different centuries are distributed in a Poisson series, find the mean number for which only one century in 20 would have four serious floods or less, and the mean number for which only one century in 20 would have 4 floods or more.

In the first case we need the first five terms of the Poisson series, so  $n = 10$ ; the table shows the 5 per cent. value of  $x^2$  is 18.307; the expectation would be 9.154 floods per century. If, on the contrary, only one century in 20 experienced 4 floods or more, the first four terms of the series would constitute 95 per cent. of the whole;

for  $n=8$ , the 95 per cent.  $\chi^2$  is 2.733, corresponding with a frequency of 1.366 serious floods per century. Unless our experience has fallen in the upper, or the lower 5 per cent. range of the distribution, the expectation lies between 1.366 and 9.154 floods per century. More or less stringent probabilities might, of course, have been chosen. Table VIII: has been constructed to make this test directly at the 10 per cent., 2½ per cent. and ½ per cent. limits. Entering the table with  $a = 4$  and  $N = \infty$ , for instance, the 2½ per cent. limits of the expectation are found to be 1.09 and 10.24.

In testing goodness of fit  $\chi^2$  is simply calculated from the numbers observed and expected in each distinguishable class. If  $m$  is the frequency expected and  $a$  that observed, then

$$\chi^2 = S \frac{(a-m)^2}{m} = S \left( \frac{a^2}{m} \right) - S(a)$$

where the summation is taken over all classes. The number of degrees of freedom is the number of classes, the frequencies of which can be varied independently without violating any totals, sub-totals, etc., which may have been used in calculating the expectations. It is inadvisable to use classes with expectations less than 5, so that these will usually be grouped in larger classes in applying the test. (See, however, Table VIII.)

The quantity  $z$  may be defined as the difference of one-half the natural logarithms of two different estimates of variance, one based on  $n_1$  and the other on  $n_2$  degrees of freedom. Table V gives values of  $z$  for different values of the three variables  $n_1$ ,  $n_2$  and  $P$ . The corresponding values of the variance ratio,  $e^{2z}$ , are given on the opposite pages. We may usually consider a  $z$  test as a test whether one estimate of a variance based on  $n_1$  degrees of freedom significantly exceeds a second estimate based on  $n_2$  degrees of freedom. We are indebted to C. G. Colcord and L. S. Deming (9) for the extension of the  $z$  table to  $P = .001$ , and to H. W. Norton, and Iowa State College, for  $P = .2$ .

The distributions of  $t$  and of  $\chi^2$  are equivalent to special cases of the distribution of  $z$ . Thus when  $n_1 = 1$ ,  $t = e^z$  and  $t^2$  for  $n_2$  degrees of freedom is the variance ratio. Equally, when  $n_2 = 1$ , the variance ratio is the value of  $1/t^2$  corresponding with the probability  $1-P$ .

When  $n_2 = \infty$ , the variance ratio is  $\chi^2/n_1$  for  $n_1$  degrees of freedom; and when  $n_1 = \infty$  it is the value of  $n_2/\chi^2$  for  $n_2$  degrees of freedom, corresponding with the probability  $1-P$ .

From the value 6 onwards the values of  $n_1$  tabulated are in harmonic progression; i.e. they are the numbers for which  $24/n_1$  takes the values 4, 3, 2, 1 and 0. As the corresponding values of  $z$  run smoothly other values of  $n_1$  may be used by interpolating for the values of  $24/n_1$ . Similarly, the largest  $n_2$  tabulated are those for which  $120/n_2$  takes the values 4, 3, 2, 1 and 0. The  $z$  values for any pair of numbers  $n_1$  and  $n_2$  can thus be found from the table. With lower accuracy the variance ratio may be similarly interpolated. For high values of  $n_1$  and  $n_2$  a useful approximation is given below the table for each value of  $P$  tabulated.

In the table of  $z$ , like that of  $\chi^2$ , the probability given, and most frequently wanted, is that of a single tail of the distribution beyond the tabulated value. For the tables of  $x$  and  $t$  it is the sum of two equivalent tails.

In addition to its general use in the analysis of variance, the  $z$  table is related to the partial sum of a binomial series in the same way as is that of  $\chi^2$  to the Poisson series. The ratio of the sums of squares is  $n_1/n_2$  times the variance ratio, or  $n_1 e^{2z}/n_2$ . If  $p:q$  is the ratio of the sums of squares,  $P$  is the sum of the first  $\frac{1}{2}n_1$  terms of the expansion of  $(q+p)^{\frac{1}{2}(n_1+n_2-2)}$ , and  $1-P$  is the sum of the remaining  $\frac{1}{2}n_2$  terms.

### Example 2

An event has occurred 3 times out of 14 trials. The probability of its occurring 3 times or less, is represented by the sum of the first four terms out of 15, hence  $n_1 = 8$ ,  $n_2 = 22$ . If  $P = 1$  per cent., the table gives a variance ratio 3.45; hence the ratio of the sums of squares is  $3.45 \times 8/22 = 1.255 = p/q$ . Thus  $p = 1.255/2.255 = .557$ . On the other hand, for the probability of its occurring 3 times or more, we need  $n_1 = 24$ ,  $n_2 = 6$ , when the variance ratio is 7.31, and  $q/p = 29.24$ ,  $p = 1/30.24 = .0331$ . Unless our experience has fallen in the upper or the lower 1 per cent. range of the distribution, the probability of occurrence lies between .0331 and .557.

This type of problem also may be examined at other levels of significance by the use of Table VIII. Entering the table with  $a = 3$ ,  $p = 3/14 = .214$ , we find that the limits of expectation, at the probability level  $P = \frac{1}{2}$  per cent., are 0.360 and 8.26, giving the corresponding limits of the probability of occurrence as .0257 and .590. If  $P = 2\frac{1}{2}$  per cent. the limits are .0466 and .508.

If the event had not occurred at all in 14 trials, it is still possible to assign an upper limit to the probability. Entering Table VIII with  $a = 0$ , and  $1/N = .0714$ , we find that the limits of expectation are 3.25 and 4.42 for  $P = 2\frac{1}{2}$  per cent. and  $P = \frac{1}{2}$  per cent. respectively, giving corresponding limits of .232 and .316 for the probability.

Table VI gives the exact test of significance for inter-class correlation coefficients. This is equivalent to the  $t$  test of the regression, which reduces to

$$t = \frac{r}{\sqrt{1-r^2}} \sqrt{n'-2}$$

for  $n'-2$  degrees of freedom, where  $n'$  is the number of pairs on which the correlation is based. The results often differ materially from the comparison of  $r$  with its standard error estimated from the formula,

$$\sigma_r = \frac{\sqrt{1-r^2}}{\sqrt{n'-1}}$$

Other comparisons involving correlation coefficients are best carried out by the  $z$  transformation provided by Table VII.

#### TABLES VI AND V2. SIGNIFICANCE OF DIFFERENCE BETWEEN TWO MEANS

Tables VI and V2 give the test of significance, due originally to Behrens, for the difference of two means for which the errors are due to different causes, so that estimates of variance cannot properly be pooled. In general we need the percentile points of a distribution compounded of two Student distributions with  $n_1$  and  $n_2$  degrees of freedom. The ratio of the scale-factors  $s_1$  and  $s_2$  is given by

$$s_1/s_2 = \tan \theta,$$

and the difference is judged to be significant if it exceeds  $d\sqrt{s_1^2+s_2^2}$ .

For each level of significance the value of  $d$  is required given the 3 known values  $n_1$ ,  $n_2$  and  $\theta$ . Table VI by P. V. Sukhatme gives the 5 per cent. and 1 per cent. points for 15° intervals of  $\theta$ , and for the lattice of values 6, 8, 12, 24 and  $\infty$  for  $n_1$  and  $n_2$ . Four-point interpolation is sufficient for full accuracy.

Table V2 deals more fully with the marginal case  $n_1 = \infty$ , where the distribution is compounded of a normal component of known variance and a component of Student's type. This occurs when we compare estimates of a physical constant, one of which is based on a large quantity of data of low precision, while the other rests on few, but rather precise, observations. When the errors from these two estimates are of comparable magnitude, both can be taken into account by finding the angle, defined by

$$\tan \theta = \sigma/s,$$

while the significant value for the observed difference is

$$d\sqrt{s^2+\sigma^2}.$$

Thus for high angles the distribution tends to normality and for low angles it tends to Student's form.

Sukhatme's values have been confirmed by the asymptotic approach used in constructing Table V2, but appear to have a very small positive bias, about .001 in  $d$ .

*Example :—*

Let us suppose that a physical constant evaluated by a new method gives a mean of twelve determinations,

$$\bar{x} = 4.77383,$$

and that the sum of the squares of the deviations of these values from their mean is

$$S(x-\bar{x})^2 = 0.011580,$$

so that from 11 degrees of freedom the variance of the mean is estimated to be

$$s^2 = 0.00008773,$$

and the estimated standard deviation of the mean is

$$s = 0.009366.$$

For 11 degrees of freedom Student's  $t$  is 2.718 at the 2 per cent. point, so that at this level of significance we should regard our observed mean as differing significantly from any value outside the limits

$$\begin{aligned} \bar{x} &\pm ts \\ &= 4.77383 \pm 0.02546 \\ &= 4.74837, 4.79929. \end{aligned}$$

If, now, numerous previous determinations, using a different method, have given the value,

$$\mu = 4.744,$$

outside these limits, it would appear that there must be a real discrepancy between the results from the two methods used.

The comparison, however, is not complete, if we realise that  $\mu$  also is not a perfectly precise determination, for it might be that though the value adopted is incompatible with the new observations, yet that both methods might be simultaneously compatible with some intermediate value of the constant.

Behrens' test enables this question to be answered, when the precision of  $\mu$  is known, by averaging the

-probability of obtaining so high a deviation, when  $\mu$  is assigned a frequency distribution instead of a fixed value. If, for example, the value of  $\mu$  adopted, has a standard error,  $\sigma$ , based on a large number of degrees of freedom, with

$$\sigma = .00382,$$

we should find,

$$\tan \theta = \sigma/s = .4079, \\ \theta = 22^\circ 12';$$

and

$$d = \frac{\bar{x} - \mu}{\sqrt{s^2 + \sigma^2}} = \frac{.02983}{.010115} = 2.949$$

Table V2 shows that at the 2 per cent. level of significance  $d$  is only 2.704 at  $20^\circ$  and 2.637 at  $30^\circ$ , for 10 degrees of freedom. For 11 degrees of freedom lower values still would be significant. The discrepancy observed is therefore a significant one, even when the errors to which  $\mu$  is liable are fully taken into account.

TABLE VIII. TESTS OF SIGNIFICANCE FOR  $2 \times 2$  CONTINGENCY TABLES

Contingency tables are normally tested for significant departures from independence by means of the  $\chi^2$  test. Provided that more than one degree of freedom is involved this test is satisfactory, even when the expectation in each class is quite small; but with only a single degree of freedom (as in  $2 \times 2$  contingency tables) the number of possible sets of values satisfying the given marginal totals is small, so that the discontinuity of the resultant distribution is marked, whereas the  $\chi^2$  distribution, which is an approximation to it, is continuous. The effect of this discontinuity can be overcome by applying Yates's correction for continuity when calculating  $\chi^2$ . This is done by reducing by  $\frac{1}{2}$  the values which are greater than expectation and increasing by  $\frac{1}{2}$  those which are less than expectation.

The correction for continuity, which should be applied when the smallest expectation is less than 500, considerably increases the effective range of the ordinary  $\chi^2$  test for a single degree of freedom; but when the smallest expectation is less than 100, the possible asymmetry of the actual distribution associated with given marginal totals becomes of importance. Such asymmetry implies that deviations of a given magnitude in one direction are less probable than those in the other.

Table VIII allows this asymmetry (and other slight deviations from the ordinary  $\chi^2$  distribution) to be taken into account. It gives what are in effect the 2.5 per cent. and 0.5 per cent. points of  $\chi_e$  (the square root of  $\chi^2$  corrected for continuity) for each tail separately. Since there are three independent marginal totals in a  $2 \times 2$  contingency table all possible contingency tables could only be completely covered by a three-dimensional table of  $\chi_e$  for each level of significance. In general, however, the distribution of  $\chi_e$  is not very different for sets of marginal totals which give the same smallest expectation, and for which the observed value in any one cell can assume the same number of values (*i.e.* tables in which the smallest marginal total is the same, this being one less than the possible number of values).

This property is utilised in Table VIII, where values of  $\chi_e$  are shown for chosen values of the smallest expectation  $m$ , and of  $p$ , the smallest expectation divided by the smallest marginal total. (For a detailed account of the method of construction of this table see Yates (14).)

In the contingency table :—

$x$	$y$	$a'$
$z$	$u$	$b'$
$a$	$b$	$n$

where  $a \leq b$ ,  $a' \leq b'$  and  $a \leq a'$ , so that  $a$  is the smallest marginal total, and  $x$  is the number in the cell with smallest expectation, we have  $m = aa'/n$ , and  $p = m/a = a'/n$ . It will be noted that as  $n$  increases with fixed  $m$  and  $p$ ,  $a$  remains fixed and  $a' : b' : n$  is constant. When  $n$  is very large the distribution of  $x$  tends to that of the binomial distribution  $(p+q)^n$ . When  $n$  takes on its smallest possible value, which is that which gives the smallest integral value of  $a' \geq a$ , the "limiting contingency distribution" of  $x$  is attained. The values of  $\chi_e$  for these two extreme distributions are shown in Table VIII, the former in ordinary type and the latter in black type. In general the intermediate contingency distributions give intermediate values of  $\chi_e$ .

Furthermore, as  $p$  tends to zero with fixed  $m$ , the expectations in all cells except that containing  $x$  become large, and the Poisson distribution is approached, whatever the ratio of  $a$  to  $a'$ . Thus for  $p = 0$  there is only one set of values in Table VIII, representing the virtual 2.5 and 0.5 per cent. points of the Poisson distributions. Thus the table can be used to test the significance of departures from binomial distributions with known  $p$  and Poisson distributions with known  $m$ , as well as for contingency tables.

*Example 3*

The number of summers (April-September) with periods of over 20 days without rainfall at Rothamsted, during this century and the last half of last century, are given in Table I.

TABLE I. SUMMERS WITH AND WITHOUT DROUGHT AT ROTHAMSTED

	1852-1900.	1901-1937.	Total.
Experiencing drought . . .	4	9	13
Without drought . . .	45	28	73
Total . . .	49	37	86

(ad-bi)  
a x b x c x d

Are the summers of the present century significantly more subject to droughts than those of the last?

$$\text{Here } \chi^2 = \frac{(9 \times 45 - 4 \times 28)^2 \times 86}{49 \times 37 \times 13 \times 73} = 4.291,$$

which would indicate significance, the 5 per cent. point for one degree of freedom (Table IV) being 3.841. Applying the correction for continuity, however, we obtain

$$\chi_c^2 = \frac{(8\frac{1}{2} \times 44\frac{1}{2} - 4\frac{1}{2} \times 28\frac{1}{2})^2 \times 86}{49 \times 37 \times 13 \times 73} = 3.124.$$

Reference to Table IV indicates that significance is not attained. This may be confirmed by reference to Table VIII. We have

$$\chi_c = 1.77, \text{ the smallest expectation } m = \frac{13 \times 37}{86} = 5.59, p = \frac{m}{13} = \frac{37}{86} = 0.43.$$

The observed set lies on the longer tail of the distribution since the number 9 with smallest expectation is greater than expectation. All the values of Table VIII ( $P = 0.025$ ) which bracket the required value lie between 1.91 and 2.06, so that significance is not attained. Notice, however, that had  $p$  been nearly zero, with the same expectation in the smallest class but with observed set on the shorter tail, the observed value of  $\chi_c$  would have indicated significance.

Linear interpolation in two dimensions in Table VIII gives the value of 1.96 for both binomial and limiting contingency distributions, indicating that at this particular point the ordinary  $\chi^2$  table (or a table of the normal probability integral, e.g. the table of probits, Table IX) gives a good estimate of the actual probability after the correction for continuity has been applied. The probit corresponding to 1.77 is 6.77, which gives a percentage of 96.16 on inverse interpolation in Table IX, corresponding to a probability of 0.0384 compared with the true value of 0.0389 calculated by the procedure given in *Statistical Methods*, Section 21.02. A method of assessing the actual probability when the values of  $\chi_c$  differ from those of  $\chi$  for the same probability levels is illustrated in Example 5.

*Example 4*

In the course of 500 spins of a roulette wheel, zero appears 24 times. What evidence is there that the wheel is biased in favour of the bank?

If the wheel is unbiased, the chance of zero occurring in any one spin is  $\frac{1}{37}$ , and zero may be expected  $\frac{1}{37} \times 500 = 13.514$  times on the average in 500 trials. The discrepancy is therefore  $10.486$ ,  $\chi^2 = \frac{10.486^2}{13.514} + \frac{10.486^2}{486.486} = 8.362$ , and  $\chi = 2.892$ .

(Note that the class of non-occurrences as well as the class of occurrences must be included when calculating  $\chi^2$ .) Inverse interpolation in Table IX gives a percentage of 99.809, which indicates that the probability of obtaining 24 or more zeros was only 0.00191. Correcting for continuity, the discrepancy becomes 9.986, and  $\chi_c^2 = 7.584$ ,  $\chi_c = 2.754$ , giving a probability of 0.00294. Referring to Table VIII, however, for  $m = 13.5$  and  $p = 0.027$  (values in ordinary type) we see that the 0.5 per cent. point of  $\chi_c$  is about 2.80, compared with the value of 2.576 given by normal theory. Thus the true probability is somewhat greater than 0.005. (True value obtained by summing the binomial distribution = 0.00559.) The omission of the correction for continuity introduces large errors, and even the use of the ordinary  $\chi^2$  table gives a probability of one half the true value.

The problem may also be solved directly by the use of Table VIII<sub>1</sub>. Since  $\alpha$  is greater than 14 we must use the approximation given for  $\alpha = 15$  and over.  $p = 24/500 = 0.048$  and therefore the conventional standard error  $\sqrt{\{a(1-p)\}} = 4.79$ . Multiplying this by the normal deviate for  $P = \frac{1}{2}$  per cent. (single tail) gives  $4.79 \times 2.576 = 12.34$ . The limits of expectation calculated from the conventional standard error are therefore 11.66 and 13.34. The corrections given by Table VIII<sub>1</sub> for these limits are +1.71 and +2.84, giving the adjusted limits of 13.37 and 39.18, corresponding to probability limits 0.0267 and 0.0784. Since  $\frac{1}{37} = 0.0270$  the probability of obtaining as many as 24 zeros in 500 spins is just over 0.005, agreeing with our previous solution.

### Example 5

Locate the upper and lower 2.5 and 0.5 per cent. points of a Poisson distribution with an expectation of 25. If  $x$  is the observed value and this is greater than expectation (*i.e.* lies on the longer tail) we have  $x_e = (x - 25 - \frac{1}{2})/\sqrt{25}$ . For  $m = 25$ ,  $p = 0$ ,  $x_e = 2.05$  for the 2.5 per cent. point, so that  $x = 35.8$ . Hence a value of 36 or over has a smaller probability than 0.025. For the 0.5 per cent. point,  $x_e = 2.76$ , so that  $x = 39.3$ , giving a value of 40 or over. Similarly, the lower 2.5 and 0.5 per cent. values of  $x$  will be found to be 15.2 and 12.6, giving integral values of 15 and 12 respectively. Normal theory would give  $x$ 's about  $\frac{1}{2}$  a unit in error for the 2.5 per cent. points and about a unit in error for the 0.5 per cent. points.

If the actual value of the probability of obtaining a value of say 14 or less is required, we may proceed as follows. At the lower 2.5 per cent. point  $x_e$  is 1.86 and  $x$  (normal theory) is 1.96, and at the lower 0.5 per cent. point  $x_e$  is 2.37 and  $x$  is 2.58. A value of 14 gives a  $x_e$  of 2.10. Hence by linear interpolation, using  $x_e$  as argument, the corresponding value of  $x$  is

$$x = 1.96 + \frac{2.10 - 1.86}{2.37 - 1.86} (2.58 - 1.96) = 2.25.$$

Reference to Table IX gives the corresponding probability as 0.0122. (True value = 0.0124.)

TABLE VIII<sub>1</sub>. LIMITS FOR THE PROBABILITY OF AN EVENT

If an event is observed to occur  $\alpha$  times out of  $N$ , a lower limit  $\pi_1$  can be assigned to the probability of this event such that if the probability were actually  $\pi_1$  then an observed number of occurrences as great or greater than  $\alpha$  out of  $N$  trials would only occur by chance with a frequency of  $P$ . Similarly an upper limit  $\pi_2$  can be assigned such that if the probability were actually  $\pi_2$  an observed number of occurrences as small or smaller than  $\alpha$  would occur with a frequency  $P$ . Corresponding to these probabilities  $\pi_1$  and  $\pi_2$  there are limits of expectation of the number of occurrences in  $N$  trials, namely  $\pi_1 N$  and  $\pi_2 N$ . These limits of expectation are tabulated in Table VIII<sub>1</sub> for  $P = 0.1$ , 0.025 and 0.005 against values of  $\alpha$  from 0 to 15 (with extension to higher values) and of  $N$  from  $2\alpha$  to  $\infty$ . The values for  $N = \infty$  gives the limits of expectation of the Poisson distribution. When  $\alpha > \frac{1}{2}N$ , the table may be entered with  $\alpha' = N - \alpha$ . Examples of the use of the table have already been given (Examples 1, 2 and 4).

TABLE VIII<sub>2</sub>. DENSITIES OF ORGANISMS ESTIMATED BY THE DILUTION METHOD

One of the methods available for estimating the number of organisms of a given type present in a medium is the dilution method. This method can be employed in cases in which the presence or absence of the organism can be determined, but in which counts cannot be made.

In the dilution method a series of suspensions of the organism,  $s$  levels in all, is prepared, each of which is  $\alpha$  times as dilute as the preceding one. Each suspension is used to inoculate  $n$  tubes with a known volume of the suspension, and the presence or absence of the organism is determined by suitable test after a period of incubation. The most accurate estimate of the number of organisms per tube at any given level is obtained by solving the equation of maximum likelihood, but it has been shown (Fisher, 30) that 87.7 per cent. of the information is contained in the total number  $X$  of fertile or  $Y$  of sterile plates, counted without regard to level. If  $\lambda$  is the number of organisms per tube at the highest concentration, the value of  $\lambda$  for which the expected average number of sterile plates is equal to the observed number is given by the equation

$$Y = n(e^{-\lambda} + e^{-\lambda/\alpha} + e^{-\lambda/\alpha^2} + \dots + e^{-\lambda/\alpha^{s-1}})$$

Table VIII<sub>2</sub> enables the solution of this equation to be obtained expeditiously for two-fold, four-fold or ten-fold dilution series of any length. All that is necessary is to calculate what may be called the mean fertile level,  $x = X/n$ , and the mean sterile level,  $y = s - x$ , and find the tabular value  $K$  corresponding to the observed  $x$  or  $y$  for the appropriate number,  $s$ , of levels. The estimate of  $\lambda$  is then given by

$$\log \lambda = x \log \alpha - K.$$

In an extended series of dilutions the value of  $K$  becomes constant for all values of  $x$  and  $y$  sufficiently distant from the ends of the distribution, except for a periodic component, which, however, is only of importance for the ten-fold series. This periodic component necessitates the special form of tabulation adopted for this series.

The average value of the variance of the number of fertile levels is  $\frac{1}{n} \log \frac{2}{\alpha}$  except at the ends of the series,

where the value increases. The average value of the variance of  $\log \lambda$  is  $\frac{1}{n} \log 2 \cdot \log \alpha$ , and this may be used in the two and four-fold series in the range where the tabular entries are substantially constant. The variance of the number of fertile levels is, however, more stable than the variance of  $\log \lambda$ . Closer approximation to the fiducial limits can therefore be found by using the average value  $\frac{1}{n} \log \frac{2}{\alpha}$  of this variance, increasing and decreasing the observed number of fertile levels by the appropriate multiple of the corresponding standard error. The table can then be re-entered to determine limiting values of  $\log \lambda$ , and thence, if required, of  $\lambda$ . This approximation is satisfactory except at the extreme ends of the range. For the same reason the number of fertile levels should be used in preference to  $\log \lambda$  when performing tests of significance, etc., on comparisons between different media. Standard errors should not be attached to  $\lambda$ .

The inclusion of tables for the four-fold and ten-fold series should not be taken to imply that the use of these series is ordinarily advisable. If an adequate number of tubes is available the two-fold dilution series should be used, with correspondingly fewer plates at each level, in preference to a four-fold or ten-fold series covering the same range. As is shown by the formula given above, the average variance of  $\log \lambda$  in the centre of the range is the same for a given total number of plates, whatever the dilution factor, but the periodicity becomes appreciable for the more coarsely spaced series.

The number of dilution levels required depends primarily on the range of populations it is desired to cover. For any given population density the majority of the information is given by the levels at which the average number of organisms per tube is near 1. Thus in a two-fold dilution series in which one dilution level has an average of exactly one organism per tube the contribution of the various levels of an infinite series to the total amount of information are as follows :

Average number of organisms per tube	more	8 and more	4	2	1	$\frac{1}{2}$	$\frac{1}{4}$	$\frac{1}{8}$	$\frac{1}{16}$ and less	
Percentage of information			0·9	12·6	26·4	24·5	16·2	9·3	4·9	5·2

For any given population density, therefore, most of the information is contributed by five levels of the series. A series of 12 dilutions will therefore amply cover a range of 100 fold, and a series of 15 dilutions a range of 1000 fold. If more than one organism which can be detected in the same set of tubes is under investigation, then longer series may be required, the exact length depending on the relative numbers of the different types of organism.

When a large number of tests involving series of the same length and with the same number of tubes at each level have to be made, the experimenter may find it convenient to prepare a special table giving  $\log \lambda$  and  $\lambda$  directly for each possible value of the total number of fertile tubes. Such a table may be easily prepared from Table VIII 2.

In practical work greater precision is often required in one part of the range than in the others. Thus the tests may have as their primary object the determination of whether the population densities are less than a given standard density, but at the same time a rough estimate of the actual population densities of samples differing widely from the standard may be of interest. In such a case the number of tubes should be increased at the levels for which the population per tube would be in the neighbourhood of 1 at the standard density, e.g. we might increase the number of tubes at levels having 4, 2, 1,  $\frac{1}{2}$  and  $\frac{1}{4}$  organisms per tube at the standard density.

For the estimation of the population densities of dilution series of this type a special table will have to be prepared. If there are  $n_1$  tubes at each of  $s$  levels and an additional  $n_2$  tubes at each of the levels from  $r+1$  to  $r'$ , the average total number of sterile tubes is given by

$$Y = n_1 y_1 + n_2 y_2 = n_1(e^{-\lambda} + e^{-\lambda/2} + \dots + e^{-\lambda/2^{s-1}}) + n_2(e^{-\lambda/2^r} + \dots + e^{-\lambda/2^{r'-1}})$$

The table can be prepared directly by calculating the values of  $Y$  for a series of values of  $\log \lambda$ , thence determining by inverse interpolation the values of  $\log \lambda$  corresponding to integral values of  $Y$ . Alternatively Table VIII 2 may be used to determine the values of  $y_1$  and  $y_2$  separately for a series of values of  $\log \lambda$ , thence performing the inverse interpolation as before. Values of  $y_2$  corresponding to values of  $\log \lambda$  falling outside the range of the table will in any case have to be computed directly, but this can be done rapidly, using the expansion of  $y_2$  in powers of  $\lambda$  for small values of  $\lambda$ .

The standard errors of estimates derived from a modified dilution series of this type naturally vary in different parts of the range. At the standard density, however, the standard errors will be those corresponding

to an infinite series of  $n_1+n_2$  tubes at each level, except for a slight increase due to the shortness of the subsidiary series.

#### Example 5. 1

Tests with potato flour containing rope spores (*B. mesentericus*) gave the following observations, using 5 tubes, each of 1 c.c., of dilutions containing 4, 2, 1, . . .,  $1/128$  g. per 100 c.c. (E. C. Barton-Wright's data).

g. per 100 c.c.	Number fertile.	g. per 100 c.c.	Number fertile.
4	5	$1/8$	3
2	5	$1/16$	2
1	5	$1/32$	2
$1/2$	5	$1/64$	0
$1/4$	4	$1/128$	0

The total number of fertile plates is 31, and the mean fertile level ( $x$ ) is therefore 6.2. Hence  $y$  is 3.8. The table gives  $K = 383$ . Hence

$$\log \lambda = 6.2 \log 2 - 383 = 1.483$$

$$\lambda = 3^{1.4}$$

The number of organisms per gram is thus estimated to be 760.

The average standard error of the number of fertile tubes is  $\sqrt{0.2}$ . The fiducial limits of the number of tubes at significance level  $P = 0.025$  are therefore  $6.2 \pm 1.976 \times \sqrt{0.2} = 5.323$  and  $7.077$ . Re-entering the table with these values, we obtain limits of 1.211 and 1.761 for  $\log \lambda$ , or 407 and 1440 for the actual number of organisms per gram. The average standard error of  $\log \lambda$  is  $\sqrt{0.0181} = 0.135$ , giving limits of  $1.483 \pm 0.264 = 1.219$  and  $1.747$  for  $\log \lambda$ , or 415 and 1400 for the actual number, which may be compared with the more exact limits given by the first method.

#### TABLES IX TO XIV. THE PROBIT AND ANGULAR TRANSFORMATIONS

Many important classes of data may be interpreted on the supposition that a normal deviate is linearly dependent on some observable concomitant measurement, and that an observable frequency is that with which this deviate is exceeded in a normal distribution. For example, the frequency with which a weight is judged to be heavier than a standard increases with the actual weight used; the frequency with which a high jumper clears a rod decreases with the height at which it is placed; the frequency with which insects survive fumigation decreases with the concentration of the fumigant. In many such cases the relation between the frequency and measurement concerned is excellently represented by considering the normal deviate corresponding to the frequency to be a linear function of the measurement, or, more frequently in toxicology, of its logarithm, the measurement being the concentration of the toxin.

Table IX gives the deviate corresponding with each thousandth of the total frequency, which is exceeded by any given frequency; by means of the difference column it is simply used to ten-thousandths. To facilitate standard methods of calculation by making all values positive, 5 has been added to the deviate. The resulting values are known as "probits." It is obvious that the probits corresponding to complementary percentages, such as 40 per cent. and 60 per cent., must add to make 10. Beyond 95 per cent. the actual differences are inserted, and beyond 98 per cent. the tabulation is by ten-thousandths. By subtracting from 10, these advantages may be made available also at the beginning of the table.

Table X, simple quantiles of the normal distribution, gives the deviates corresponding with proper fractions. The proper fractions, up to  $\frac{1}{2}$ , having denominators up to 30, are here arranged in order of magnitude. When small numbers are involved this table enables the probits to be found more expeditiously than does Table IX.

#### Example 6

What deviate is exceeded by  $4/17$  of a normal curve? The deviate given is 0.7215, so that if 4 animals survive out of 17 the probit is 5.7215. The same value may be obtained by expressing  $13/17$  as a decimal, 0.7647, and referring to Table IX.

When tests have been made on several concentrations it is usual to fit a straight line expressing the probit in terms of the logarithmic concentration. The weight assigned to each point will be the number of animals used in determining it multiplied by the weighting coefficient given in Table XI. It is best to draw a provisional line graphically, and obtain the weighting coefficients from the probits read from the graph. Some

workers prefer to draw a provisional line by calculation, using weighting coefficients based on the probits empirically observed. This leads to some ambiguity when at any concentration all die (or all survive), for such observations nominally give an infinite probit with zero weight.

However the provisional line be obtained, it should for refined purposes, such as tests of significance, be replaced by one based on working probits obtainable from Table XI. The cases in which all animals die are assigned the maximal working probit, given in the 2nd column; other cases are assigned values lower by the product of the fraction observed to survive multiplied by the range, given in the 3rd column. The working probit so obtained is given a weight found by multiplying the total number of animals on which it is based, by the weighting coefficient shown in the 4th column of the table. Any tolerably good provisional line will give a satisfactory result when this process is applied. An excellent account of the treatment of toxicological data has been given by C. I. Bliss (4-7). The case is also discussed, from the point of view of amount of information, in *The Design of Experiments* (2).

### Example 7

The following survival fractions were obtained on testing sets of eight brine-shrimps, *Artemia salina*, from a single brood, in arsenical solutions having concentrations in geometric progression.

Solution	C	D	E	F	G	H	I
Total tested	8	8	8	8	8	8	8
Survived	8	8	6	5	5	1	0

Since, using strengths *C*, *D* and *I*, all or none have survived, the tests with solutions *E* to *H* are available for plotting probit values, in order to obtain a provisional line. A sufficiently good line may usually be drawn graphically. A second serviceable method is to fit a straight line, without weighting, to the probits available. Thus, using Table X, we have

Solution	Empirical Probit.
<i>E</i>	4.33
<i>F</i>	4.68
<i>G</i>	4.68
<i>H</i>	6.15
<hr/>	<hr/>
Total	19.84
Mean	4.96

The slope from four equally spaced points is

$$b = \frac{3(H-E)+(G-F)}{3^2+1^2} = .546.$$

It is worth while giving some attention to obtaining a satisfactory preliminary fit, since otherwise the fitting process may have to be repeated. It is also desirable to avoid interpolation by choosing simple values. The inclusion of *C*, *D* and *I* will certainly tend to increase the slope, and may lower the average probit. For *b*, therefore, we take the value .6, and take the probit midway between *F* and *G* to be 4.9. The provisional expected probits are those shown in the 3rd column of Table 2.

TABLE 2.

Solution.	Independent Variate <i>x</i> .	Provisional Probit <i>Y</i> .	Working Probit <i>y</i> .	Weight <i>w</i> .	<i>wy</i> .
<i>C</i>	3	2.8	2.4081	.7343	1.7683
<i>D</i>	4	3.4	2.9060	1.9002	5.5220
<i>E</i>	5	4.0	4.3775	3.5090	15.3606
<i>F</i>	6	4.6	4.6826	4.8042	22.4961
<i>G</i>	7	5.2	4.6776	5.0193	23.4783
<i>H</i>	8	5.8	6.0998	4.0208	24.5261
<i>I</i>	9	6.4	6.9394	2.4159	16.7649
				22.4037	109.9163

The remainder of Table 2 is then filled by using Table XI.

When all die, as for solution *I*, the working probit has its maximal value, given in the 2nd column of Table XI. This is 6.9394, or .5394 above expectation. (In the calculations for fitting, we may use either the working probits themselves to obtain the actual constants of the fitted line, or their deviations from provisional expectations to obtain adjustments of the constants provisionally adopted. Table 2 is arranged to show the first method.)

When the provisional probit is below 5, we may subtract it from 10, and finally subtract the working probit obtained from 10, interchanging the numbers of dead and living. Thus for *C* we find 2.4081; and, for *D*, 2.9060.

More generally, we subtract from the maximal probit a fraction of the range (3rd column of Table XI) equal to the proportion of survivors; so *G* gives

Maximal working probit	6.2759	Range 2.5573
Range $\times 5/8$	1.5983	
Working probit	4.6776	

while for *H* we have, similarly, 6.0998.

For *E*, if all had *lived*, we should have 3.3443, but as one-quarter have died we add one-quarter of 4.1327, giving 4.3775, while for *F* we find, similarly, 4.6826.

In all cases the weight assigned to the evidence of each solution is the weighting coefficient, corresponding with the provisional probit, multiplied by the number of individuals tested.

From the sum of the weights, and the weighted sums of *x* and *y*, we obtain the values of  $\bar{x}$  and  $\bar{y}$  according to the formulæ.

$$\bar{x} = \frac{S(wx)}{S(w)}, \quad \bar{y} = \frac{S(wy)}{S(w)}.$$

It is convenient to calculate  $S(wx^2)$  at the same time as  $S(wx)$ ; for calculating these any suitable origin such as *F* (*x* = 6) may be used. The reduced sum of squares of the independent variate is then

$$A = Sw(x - \bar{x})^2 = S(wx^2) - \bar{x}S(wx).$$

With most types of machine, the values of *wy* will be written down and summed as in Table 2; from these it is easy to obtain the reduced sum of products,

$$B = Swy(x - \bar{x}) = S(wxy) - \bar{x}S(wy).$$

These quantities are all that are needed for adjusting the regression line. For testing goodness of fit we also calculate

$$C = Sw(y - \bar{y})^2 = S(wy^2) - \bar{y}S(wy).$$

Turning to the numerical values of Table 2, we may note that the three solutions first omitted contribute nearly one quarter of the total weight, and a still higher proportion to *A*, or to the amount of information supplied as to the slope of the line. For the others the working probits differ not greatly, but appreciably, from the empirical probits first used.

Numerically, Table 2 gives

$S(wx)$	10.7963	$S(wx^2)$	60.5641	$S(wxy)$	91.1157
$\bar{x}$	4.81898	<i>A</i>	55.3614	<i>B</i>	38.1473
$\bar{y}$	4.906167			<i>b</i>	.68906

The recalculated slope,  $b = B/A$ , is .68906. This is considerably higher than the provisional value, .6. Accepting this solution, the 50 per cent. death point is found when  $Y = 5$ , that is .093833 above  $\bar{y}$ . We have, therefore,

$$6.481898 + \frac{.093833}{.68906} = 6.618$$

as the estimated 50 per cent. death point.

For goodness of fit we find

$$\begin{aligned} S(wy^2) &= 568.6512 \\ C &= 29.3835 \\ x^2 = C - Bb &= 3.0977 \quad n = 5 \end{aligned}$$

Since two constants have been fitted there are five degrees of freedom, so that there is no indication of departure from the form of the theoretical expectation. In these circumstances the variance of the estimated 50 per cent. death point may be taken to be

$$s^2 = \frac{1}{b^2} \left\{ \frac{1}{S(w)} + \frac{(x - \bar{x})^2}{A} \right\}$$

Numerically,

$1/S(w)$	$\cdot 044635$
$(\cdot 136)^2/A$	$\cdot 000334$
	<hr/>
	$\cdot 044969$
$b_s$	$\cdot 21206$

The standard sampling error of the estimate is therefore  $\cdot 308$ .

Had  $x^2$  been excessive, indicating causes of disturbance other than random sampling, the estimated variance would be multiplied by  $x^2/n$ ; unless, of course, the theory that the probits are linear functions of  $x$  has to be abandoned.

The example has been chosen to illustrate the expeditious use of the tables. No interpolation has been employed, as it would be if the process were repeated, using the results of the first fit as a new provisional line. It is, therefore, of interest, as an indication of the precision to be expected, that a much more precise fit gives  $6\cdot609 \pm \cdot317$  for the 50 per cent. point, showing that this value and its precision have been very satisfactorily estimated. The slope, estimated at  $\cdot6891 \pm \cdot1344$ , is not so good, since the more exact value is  $\cdot7126 \pm \cdot1574$ . Here the error exceeds a tenth of the standard error of random sampling, so that, if the slope were of importance, a second fitting would have been justified. Finally, from the more exact fit we find  $x^2 = 3\cdot773$  in place of  $3\cdot098$ , confirming the agreement with expectation, but showing also that had this been doubtful a more exact fitting might have resolved the doubt.

The normal transformation may be looked upon as one of a series of methods of transforming percentages into more suitable variables. Of these the transformation of a probability varying from 0 to 1 into an angle varying from  $0^\circ$  to  $90^\circ$ , according to the relationship

$$p = \sin^2 \phi$$

is remarkable in that the amount of information concerning  $\phi$  is constant. In consequence, in large samples, the sampling variation tends to normality with a variance which depends only on the number of observations on which the percentage is based. The weighting coefficient for this transformation is constant. In other respects Tables XII to XIV afford the same facilities for handling percentages transformed in this way as do Tables IX to XI for the normal transformation. This transformation is equivalent to replacing the normal curve by one of which the ordinate is  $\sin 2\phi$ .

A third transformation of some interest which is readily available from these tables, is given by

$$\begin{aligned} z &= \frac{1}{2}(\log_p p - \log_q q) \\ \text{or} \quad p &= e^{2z}/(1+e^{2z}). \end{aligned}$$

If  $r = 2p-1$ , the values of  $z$  are given in Table VII. With this transformation we may use

$$\begin{array}{ll} \text{Maximal working } z & Z + \frac{1}{2P} = Z + \frac{1}{1+R} \\ \text{Range} & \frac{1}{2PQ} = \frac{2}{1-R^2} \\ \text{Weighting coefficient} & 4PQ = 1-R^2 \end{array}$$

where  $Z$  is the expected value of  $z$  given by any provisional fitting, and the value of  $R$  is taken from that of  $Z$ , using Table VII. This transformation is equivalent to replacing the normal curve by one of which the ordinate is  $\frac{1}{2} \operatorname{sech}^2 z$ .

In addition to their toxicological and similar applications, transformations are of use in the analysis of material which has a very skew distribution, for the purpose of equalising the variance of quantities of widely different magnitudes which it is desired to include in the same analysis, and for the purpose of reducing the observations to a scale on which the effects of associated variables are more nearly constant. Thus when it is required to perform an analysis of variance on a set of percentages, e.g. of the deaths of seedlings obtained from plots of a replicated experiment, it is frequently advantageous to transform these percentages by means of the angular transformation. As we have seen, this has the effect, in large samples, of equalising the component of variance due to sampling, when each percentage is based on the same number of observations. The square root transformation

$$y = \sqrt{x}$$

has the same property when the observations on each plot are distributed according to a Poisson distribution. This transformation is equivalent to the angular transformation at each end of the percentage scale. (In this connection see W. G. Cochran (8).)

The logarithmic transformation

$$y = \log x$$

is useful when dealing with material on which the effects of other variables may be expected to be proportional to the numbers involved. The influence of a given increase in temperature on the number of insects caught in a light trap, for example, is likely to be proportional to the number of active insects, in which case the increment in the logarithm of the catch will be the same whatever the number of insects, unless some of the numbers are very small. In this connection it may be noted that the transformation  $y = \log(x+1)$  is sometimes convenient, being substantially equivalent to  $y = \frac{1}{2}\sqrt{x}$  when  $x$  is less than 10 and to  $y = \log x$  for larger numbers.

A further use of transformations is for the purpose of facilitating interpolation by obtaining a transformed function which is much more nearly linear. One example of this, the use of the reciprocals of  $n_1$  and  $n_2$  in interpolation in the table of  $z$  (Table V), has already been mentioned. The logarithmic transformation and the transformation of Table VII have frequently proved of use when dealing with functions whose argument is a probability.

#### TABLES XV AND XVI. LATIN SQUARES

Latin squares of size  $7 \times 7$  and smaller have been enumerated (11), (22). For  $4 \times 4$  and  $5 \times 5$  squares all the standard squares (*i.e.* squares with first row and first column in the standard order) are shown in Table XV, except that only one of each pair of conjugate  $5 \times 5$  squares is given (two standard squares are conjugate if the rows of one are the columns of the other). From each  $4 \times 4$  standard square  $4!3! - 1$  non-standard squares, all different, may be generated by permuting all the rows except the first, and all columns. Thus each  $4 \times 4$  standard square represents a set of 144 squares. There are consequently  $4 \times 144$  or 576  $4 \times 4$  Latin squares. Similarly, there are  $56 \times 2880$  or 161,280  $5 \times 5$  Latin squares. There is one  $2 \times 2$  standard square and one  $3 \times 3$  standard square, giving two  $2 \times 2$  squares and twelve  $3 \times 3$  squares in all.

For  $6 \times 6$  squares one square of each transformation set (*i.e.* set generated from one of its members by permutation of rows, columns, and letters), or of each pair of conjugate transformation sets, is shown. Such permutation of rows, columns and letters will generate  $(6!)^3$  or 373,248,000 squares, of which  $6 \times 6!$  or 4320 are standard squares. These squares are, however, not necessarily all different, the largest number actually obtained in any one  $6 \times 6$  set being one-quarter of the possible number, *i.e.* 1080 standard squares, and the smallest number one 216th, *i.e.* 20 standard squares. The actual numbers in each transformation set are shown in the table. There are in all 9408 standard  $6 \times 6$  squares, giving 812,851,200  $6 \times 6$  squares in all.

By permuting with each other the three categories, rows, columns, and letters, six sets are formed, not necessarily all different. These sets are said to be *adjugate*. In the case of the  $6 \times 6$  squares each pair of conjugate sets and the set immediately following them in the table form an adjugate trio of sets. The remaining sets are self-adjugate.

Norton (1939) has enumerated 562 sets of  $7 \times 7$  squares, of 146 species, containing 16,927,968 standard squares. Four examples are shown in the table. Square (a) is a member of a transformation set in which the squares generated by the permutation of rows, columns and letters are all different. It thus contains  $(7!)^3$  or 128,024,064,000 squares, of which  $7 \times 7!$  or 35,280 are standard squares. The sets generated by the adjugate permutations are also all different. The example thus stands for an aggregate of 211,680 standard squares. No Graeco-Latin squares can be formed with any of these.

Square (b) differs from square (a) only by the interchange of two pairs of letters; *B* and *C* in the 5th and 6th columns. It belongs to a set of only 11,760 standard squares, which is one of an adjugate trio of sets, giving 35,280 standard squares in all. One-seventh (1680) of the standard squares of one of these sets are self-conjugate. Again no Graeco-Latin square can be formed.

The third illustration is a Graeco-Latin square, with the fourth category (Greek letters) represented by numeral suffices. No fifth category can be added. The suffices are standardised by assigning them in their natural order to the first row. The Latin square involved is one of a set of only 210 standard Latin squares, but the same transformation of the Graeco-Latin square yields a set of 1680 standard Graeco-Latin squares, containing eight different standard arrangements of the suffices in each Latin square. These eight solutions are in fact all that exist, so that this set of Latin squares belongs to only one Graeco-Latin set. Permutation of the three categories, rows, columns, and letters, yields the same set, but if suffices are interchanged with rows, columns, or letters, three more sets of 1680 standard Graeco-Latin squares are formed (6720 in all).

The three new sets all involve the cyclic Latin square shown as the fourth example. There are only 120 standard Latin squares in this set, so that each has 14 solutions in each of the Graeco-Latin sets, or 42 in

all. Under orthogonal squares are given six  $7 \times 7$  squares, of which the first is the above Latin square, while the rest are five more Graeco solutions which belong to a second set and are mutually orthogonal.

Little is known about squares larger than  $7 \times 7$ , other than the orthogonal properties of the special sets shown in Table XVI. In Table XV a single example of each size from  $8 \times 8$  to  $12 \times 12$  is given. These examples will suffice (after permutation of rows, columns, and letters at random) for experimental arrangements requiring Latin squares of these sizes.

To select a square at random from all possible squares of a given size up to  $6 \times 6$  proceed as follows:

- (1) Select one of the given squares by using the key numbers printed below each square, selecting a number at random from all possible key numbers. If the key number falls in the second of two groups use the conjugate square.
- (2) In the case of  $3 \times 3$ ,  $4 \times 4$ , and  $5 \times 5$  squares permute all rows except the first of the selected square, and all columns. Alternatively permute all rows except the first and assign the letters to the treatments at random. For  $6 \times 6$  squares permute all rows and all columns at random, and then assign the letters to the treatments at random.

Table XVI gives complete sets of orthogonal Latin squares of sides 3, 4, 5, 7, 8, and 9. Two Latin squares are orthogonal to each other if, when they are superimposed, every letter of one square occurs once and once only with every letter of the other. Such a pair of squares (one square being written with Greek and the other with Latin letters) form a Graeco-Latin square.

If a complete set of  $p-1$  orthogonal squares of side  $p$  exists, the  $p^2-1$  degrees of freedom corresponding to the contrasts of the  $p^2$  cells of the square split up into  $p+1$  sets of  $p-1$  degrees of freedom, corresponding to the contrasts between the rows, between the columns, and between the letters of each of the  $p-1$  squares. A set of less than  $p-1$  orthogonal squares gives a similar but incomplete partition.

Complete sets of orthogonal squares are known to exist for all prime numbers and for  $p=4, 8$  and  $9$ . (See *The Design of Experiments*.) The rule of formation for all prime numbers will be apparent from the inspection of the sets for  $p=5$  and  $p=7$ , each row being formed by moving the previous row 1, 2, 3 . . . places to the left.

The rows of the  $8 \times 8$  squares may be taken to represent the 8 combinations of three two-level factors  $A$ ,  $B$ , and  $C$ , in the order (1),  $a$ ,  $b$ ,  $ab$ ,  $c$ ,  $ac$ ,  $bc$ ,  $abc$ , and the columns may be taken to represent the similar combinations of a further three factors  $D$ ,  $E$ , and  $F$ . The 64 cells of each square will then represent the 64 combinations of the 6 factors. The numbers of each square will divide these combinations into 8 groups of 8, the contrasts among which will represent a set of 7 degrees of freedom orthogonal to  $A$ ,  $B$  and  $C$  and their interactions, and to  $D$ ,  $E$ , and  $F$  and their interactions, and also to the six other sets of seven degrees of freedom given by the other six squares. In the squares shown these degrees of freedom correspond to specific interactions between the six factors. The interactions corresponding to 3 degrees of freedom from each set are shown in the table, the remainder being given by the "generalised" interactions of these three. Note the law of formation of each set from the preceding one, corresponding to the cyclic interchange of all the rows of the square except the first.

The set of  $9 \times 9$  squares possesses similar properties. The actual degrees of freedom confounded, when the cells of the squares represent the 81 combinations of four factors at three levels, are given in terms of the notation developed by Yates (3).

Besides their use in ordinary factorial design, complete sets of orthogonal squares serve as the basis of quasi-factorial and quasi-Latin square designs (balanced lattices and lattice squares) and also serve to generate other designs in balanced incomplete blocks. (See (14), (15), (16), (17), and Tables XVII-XIX.) Pairs and larger incomplete sets of orthogonal squares (Graeco- and hyper-Graeco-Latin squares) also provide designs for varietal trials superseding the so-called semi-Latin squares (3).

An orthogonal pair of squares exists for all odd numbers, being formed of two "diagonal" squares (squares of the type of the  $5 \times 5$  squares I and IV). Such a pair also exists for all numbers which are multiples of 4. The process of generation, which depends on the existence of orthogonal pairs of squares for factors of the number, may be illustrated for a pair of  $12 \times 12$  squares. Let  $a$  and  $a'$  represent the  $4 \times 4$  squares I and II,  $\beta$  and  $\beta'$ , and  $\gamma$  and  $\gamma'$ , the same squares with 1, 2, 3, 4 replaced by 5, 6, 7, 8 and 9, 10, 11, 12 respectively. Then

$$\begin{array}{ccc} a & \beta & \gamma \\ \beta & \gamma & a \end{array} \quad \text{and} \quad \begin{array}{ccc} a' & \beta' & \gamma' \\ \gamma' & a' & \beta' \\ \beta' & \gamma' & a' \end{array}$$

form an orthogonal pair of  $12 \times 12$  squares. The process will generate larger orthogonal sets if such sets exist for both factors of the number. Thus there will be a set of three squares of side 20.

It has been shown that no orthogonal pair of  $6 \times 6$  squares exists, but larger even numbers not divisible by 4 have not been investigated.

### TABLES XVII TO XIX. BALANCED INCOMPLETE BLOCKS

If  $v$  varieties (or treatments) are to be compared in randomized blocks of  $k$  experimental units ( $k$  being less than  $v$ ), block differences can be simply eliminated if the arrangement is such that every two varieties occur together in the same number ( $\lambda$ ) of blocks. If  $r$  is the number of replicates, and  $b$  the number of blocks, the number of experimental units is  $rv (= bk)$ , and  $\lambda = r(k-1)/(v-1)$ . Examples of experimental material and processes in which this type of arrangement, called *balanced incomplete blocks*, is likely to be of use are: litters of animals, monozygotic twins and other paired material, laboratory and technological processes in which the nature of the process or the apparatus available imposes a definite limit on the number of treatments in a group, agricultural experiments on commercial farms when each farm is only prepared to undertake a small number of treatments, and varietal trials involving a large number of varieties. (See also Yates (16).)

Arrangements satisfying the required conditions are clearly provided by taking all possible combinations of the  $v$  varieties,  $k$  at a time, but if  $v$  is at all large, the number of replicates required will be very large. Arrangements involving fewer replicates are therefore of importance. Tables XVIII and XIX give indexes, by number of replications ( $r$ ), and by number of units in a block ( $k$ ) respectively, of the arrangements requiring ten or less replications which are known to exist; and of all arithmetically possible arrangements, the existence of which has not been disproved. In one or two cases such existence is definitely improbable.

The combinatorial solutions which are referred to by numbers are shown in Table XVII. Those involving all combinations are indicated by  $u$  (unreduced), and the two series derivable from sets of orthogonal squares (described below) by  $o.s.$  Cases not yet solved are indicated by a dash (—). When  $k > \frac{1}{2}v$  arrangements can be obtained from arrangements for the same number of varieties in blocks of  $v-k$  units, by replacing each block by its complement, i.e. by a block containing all the varieties missing from the original block.

Some of the combinatorial solutions are derivable very simply by cyclic substitutions. In such cases one block only for each family is given in Table 17. In solution number 2, for example, the block  $aefgi$  is given. The contents of the other 10 blocks are obtained progressively by replacing each letter by the next in order, with the convention that the last letter  $k$  is followed by  $a$ . Thus the blocks are  $aefgi, bfgij, cghik, dhija$ , etc.

For the dicyclic solutions a similar procedure holds. In solution number 5, for example, the 16 varieties are represented by 4 letters in combination with 4 suffices. The 16 blocks are generated by performing the cyclic substitution on the letters (thus obtaining 4 blocks) and then performing the cyclic substitution on the suffices of each of these 4 blocks.

One of the cyclic solutions, No. 29, and one of dicyclic solutions, No. 12, consists of two families, each family being generated by a cyclic or dicyclic substitution of the above type.

Two series of arrangements and their complements are derivable from complete sets of orthogonal Latin squares (Table XVI). In the first, for  $p^2$  varieties in  $p(p+1)$  blocks of  $p$  plots ( $r = p+1, \lambda = 1$ ), each of the  $p^2$  cells of the set of squares is taken to represent a variety, the blocks being determined by the rows, the columns and the numbers of the  $p-1$  squares. In the second, for  $p^2+p+1$  varieties in  $p^2+p+1$  blocks of  $p+1$  plots ( $r = p+1, \lambda = 1$ ),  $p^2$  of the varieties are divided as in the first arrangement, each of the  $p+1$  additional varieties being allotted to one of the  $p+1$  sets of blocks so formed, while the last block consists entirely of these additional varieties. Thus the set of  $4 \times 4$  squares gives the following arrangements for 16 and 21 varieties (the latter including the bracketed varieties) :

$a b c d (q)$	$a e i m (r)$	$a f k p (s)$	$a g l n (t)$	$a h j o (u)$	$(q r s t u)$
$ef g h (q)$	$b f j n (r)$	$b e l o (s)$	$b h k m (t)$	$b g i p (u)$	
$i j k l (q)$	$c g k o (r)$	$c h i n (s)$	$c e j p (t)$	$c f l m (u)$	
$m n o p (q)$	$d h l p (r)$	$d g j m (s)$	$d f i o (t)$	$d e k n (u)$	

The second of these series, at least up to 10 replications, may also be generated by the cyclic substitutions shown in Table 2.1. For convenience the varieties are here represented by numbers instead of letters. The first series may then be obtained from the second by deleting any set of varieties occurring in the same block.

TABLE 2. I. CYCLIC SOLUTIONS FOR BALANCED INCOMPLETE BLOCKS

Problem.	Modulus (v).	Selected numbers.
O. S. 2	7	1, 2, 4
O. S. 3	13	1, 2, 4, 10
2	11	1, 5, 6, 7, 9
O. S. 4	21	1, 4, 5, 10, 12
O. S. 5	31	1, 2, 4, 11, 15, 27
9	15	1, 2, 3, 5, 6, 9, 11
O. S. 7	57	1, 4, 6, 14, 15, 21, 33, 37
19	19	1, 3, 5, 6, 7, 8, 11, 14, 15
23	37	1, 2, 4, 8, 18, 25, 26, 30, 36
O. S. 8	73	1, 2, 4, 8, 16, 32, 37, 55, 64
O. S. 9	91	1, 2, 7, 11, 24, 27, 35, 42, 54, 56

See also the dicyclic solutions in one family (No. 5), in two families (No. 13), and the cyclic solution in two families (No. 29) of Table XVII.

### Youden's Squares

It has been shown (Youden, 21) that when  $b = v$  it is possible, at least in the cases of practical importance, so to arrange the order of the varieties in the blocks that each variety occurs once in each position in the block, and it is thus possible to eliminate experimental differences between these positions, each of which comprises a complete replication.

For example, experimental material consisting of 13 plants each with 4 corresponding leaves may be assigned to 13 treatments so that each treatment occurs once on each type of leaf. At the same time the 13 plants constitute randomized blocks of 4 treatments each, in which each treatment occurs on the same plant once with every other treatment. Similarly a varietal trial of 13 varieties in blocks of 4 may be arranged on the ground in a  $4 \times 13$  rectangle of plots so that both row and column differences are eliminated from the varietal comparisons.

In drawing up an actual experimental arrangement of this type the blocks should be assigned to the plants (or arranged on the ground) at random, and the experimental treatments (or varieties) should be similarly assigned to the letters.

A cyclic or dicyclic substitution which gives an incomplete block solution will also give the corresponding Youden square, provided that each block is written in the order in which it is generated. The complementary Youden square solution may be obtained by performing the same cyclic substitution on the block which is complementary to the given block.

Cyclic solutions in two families provide an extension of Youden squares. In these the differences corresponding to the positions in the blocks of each family may be eliminated, e.g. 9 degrees of freedom in solution No. 29 for 10 replicates of 41 varieties.

Besides balanced incomplete blocks and Youden squares a number of different types of non-balanced arrangement are also available, namely quasi-factorial arrangements, described in (25) and (26), lattice squares (27), and partially balanced arrangements (28). The various types of arrangement are reviewed in (3) and (29). The experimenter should acquaint himself with their advantages and disadvantages before deciding which is most appropriate for his own needs.

### Analysis of Balanced Incomplete Block Experiments

In the analysis of incomplete block experiments the block differences may be eliminated entirely from the varietal comparisons (Yates, 16), or, as has been shown later (Yates, 23), the information contributed by these comparisons may be combined with that provided by the intra-block comparisons, with weights depending on the relative accuracy of the two sets of comparisons (as estimated from the experimental results).

If the choice of blocks has been successful in substantially reducing the variability of the material, then the amount of information contributed by the inter-block comparisons will be small, but in the limiting case when the inter-block and intra-block comparisons are of equal accuracy, the fraction of the total information contained in the inter-block comparisons is given by the efficiency factor  $E = \frac{1 - 1/k}{1 - 1/v} = \frac{v\lambda}{rk}$ , which approaches the value  $\frac{1}{2}$  when  $k = 2$  and  $v$  is large.

In general, therefore, it is worth recovering the inter-block information, except in small experiments with less than 10 degrees of freedom for blocks, in which the relative weights cannot be determined with sufficient accuracy. If the method described below is followed the amount of additional computation is not great.

Sometimes the blocks may be arranged in groups so as to minimise the inter-block variance. Each such group must contain an equal number of replicates of each variety. In general it is not possible so to arrange things that each group of blocks contains only a single replication. Such groups as are possible in the designs of Table XVII are indicated in the table itself. Within each group the arrangement of the blocks should be at random.

If  $V_s$  be the sum of all the yields of variety  $s$ ,  $T_s$  the sum of all the block totals of blocks containing variety  $s$ ,  $T'$  the sum of all the remaining block totals, and  $G$  the total yield of all plots, the estimates of the varietal differences derived from the intra-block comparisons are obtained from the quantities

$$Q_s = V_s - T_s/k,$$

or, as is more convenient when  $k > \frac{1}{2}v$ ,

$$Q'_s = V_s + T'/k.$$

The actual differences in units of the total yield of the  $r$  replicates are given by the differences of

$$Q_s/E \text{ or } Q'_s/E,$$

the sum of the first set being zero, and the second set  $rG/\lambda v$ .

The error variance of these latter sets of quantities is  $r/Ew$ , where  $1/w$  is the intra-block error variance.

The estimates of the varietal differences derived from the inter-block comparisons are similarly given by the differences of

$$rT_s/(r-\lambda) \text{ or } rT'_s/(r-\lambda),$$

in units of the total yield of  $r$  replicates. The error variance of these sets of quantities is  $kr^2/(r-\lambda)w'$ , where  $1/w'$  is the error variance of the inter-block comparisons, in units of a single plot.

The most efficient estimates of the varietal differences are given by the quantities

$$Y_s = V_s + \mu W_s$$

where

$$W_s = (v-k)V_s - (v-1)T_s + (k-1)G,$$

and

$$\mu = \frac{w-w'}{wv(k-1)+w'(v-k)}.$$

The error variance of the  $Y_s$ 's is

$$\frac{kr(v-1)}{wv(k-1)+w'(v-k)}$$

The analysis of variance follows the lines shown in the accompanying table, in which  $dev^2$  indicates the sum of squares of the deviations,  $y$  the individual yields and  $B$  the block totals. If recovery of inter-block information is not required then only the part (a) of the analysis of variance is required. There is also no need to subdivide the sum of squares for blocks, ignoring varieties. The comparison of the mean square (a) for varieties with intra-block error gives an exact test of significance for the intra-block estimates.

Method (a).	D.F.	S.S. (a).	S.S. (b).	Method (b).
Blocks (ignoring varieties) :				Blocks (eliminating varieties) :
Varietal component	$v-1$	$\frac{dev^2 T}{k(r-\lambda)}$	$\frac{dev^2 W}{rv(v-k)(k-1)}$	Varietal component
Remainder	$b-v$	†	†	Remainder
Total	$b-1$	$\frac{dev^2 B^*}{k}$	†	Total
Varieties (eliminating blocks)	$v-1$	$\frac{dev^2 kQ}{k^2 rE}$	$\frac{dev^2 V}{r}$	Varieties (ignoring blocks)
Intra-block error	$rv-v-b+1$	†	↔ ↔ †	Intra-block error
Total	$rv-1$	$dev^2 y^*$	$↔ ↔ dev^2 y^*$	Total

\* Requires checking.

† Calculated by addition or subtraction.

If the mean square for intra-block error is  $M$  and the mean square ( $b$ ) for the  $b-1$  degrees of freedom for blocks, eliminating varieties, is  $M'$ ,  $w$  and  $w'$  are estimated from the equations

$$w = \frac{1}{M'}, \quad w' = \frac{v(r-1)}{k(b-1)M' - (v-k)M}$$

If  $M'$  is less than  $M$ ,  $w'$  may ordinarily be taken as equal to  $w$ .

If the structure of the design is such that the blocks fall into  $r$  groups, each containing a single replication of all the varieties (as in solutions Nos. 6, 7 and 25), and each of these groups of blocks is itself arranged in a large block, then the sum of squares corresponding to the  $r-1$  degrees of freedom for complete replications must be eliminated from the sums of squares for blocks. The formula for  $w'$  will then become

$$w' = \frac{r-1}{rM' - M}$$

In the more general case in which there are  $c$  such groups of blocks, each containing  $r/c$  replications, we have

$$w' = \frac{v(r-1) - k(c-1)}{k(b-c)M' - (v-k)M}$$

In the case of a Youden square the sum of squares corresponding to the  $k-1$  degrees of freedom for the  $k$  series (representing leaf position, etc.) must be eliminated from the intra-block error.

#### Example 8

Table 3 shows the scores of 18 litters of 4 rats in a discrimination test, the values shown being the square roots of the number of trials prior to 12 consecutive successful trials (the data are a random selection from scores published by F. A. E. Crew (10)). A dummy trial of 9 treatments (e.g. dietary treatments) in blocks of 4, corresponding to litters, is superimposed on these scores. (Design II of Table XVII,  $r=8$ ,  $v=9$ ,  $k=4$ ,  $b=18$ ,  $\lambda=3$ .)

TABLE 5. ANALYSIS OF VARIANCE, DISCRIMINATION TEST

	D.F.	S.S. (a)	S.S. (b)	M.S.
Blocks :				
Varietal component	8	41.4684	37.0634	4.6329 (b)
Remainder	9	138.2011	138.2011	15.3557
Total	17	179.6695	175.2645	10.3097 (b)
Varieties	8	19.6044	24.0094	2.4506 (a)
Error	46	119.4506	119.4506	2.5968
Total	71	318.7245	318.7245	—

From the results of the analysis of variance we obtain

$$w = \frac{1}{2.5968} = 0.3851, w' = \frac{63}{68 \times 10.3097 - 5 \times 2.5968} = 0.0916$$

$$\mu = \frac{0.3851 - 0.0916}{27 \times 0.3851 + 5 \times 0.0916} = \frac{0.2935}{10.8557} = 0.02704$$

The final adjusted scores in terms of the total scores of eight rats are given in the last column of Table 4. The standard error of these scores is

$$\sqrt{\frac{256}{10.8557}} = \sqrt{23.58} = 4.86$$

The scores based on intra-block information only (which are equal to  $Q/E + \frac{1}{2}G$ ) are also shown in Table 4. Their standard errors are

$$\sqrt{(8 \times 2.5968 \times 27/32)} = \sqrt{24.62} = 4.96$$

Thus the gain in information from the recovery of the inter-block information is  $24.62/23.58 - 1$  or 4.4 per cent. (excluding losses due to inaccuracy of weighting). The gain is here trivial, but if inter-litter and intra-litter comparisons had been of equal accuracy, the gain would have been 18.5 per cent.

The litter totals can be adjusted to allow for the effects of the treatments by deducting one-eighth the scores based on intra-litter differences only of each of the four treatments contained in the litter concerned from the total of that litter (adding four times the general mean if desired). Thus the adjusted total of the first litter is  $24.6 - 4.20 - 5.76 - 4.76 - 5.20 + 4 \times 4.92 = 24.36$ .

#### TABLES XX AND XXI. ORDINAL (OR RANKED) DATA

It is often necessary to draw statistical conclusions from data giving the order of a number of magnitudes without knowledge of their quantitative values. Thus in tests of psychological preference subjects can often express preferences, without being able to assign numerical values to the force with which the preference is felt. Not infrequently, also, an experimenter who possesses quantitative values may suspect that the metric

used is unsuitable to the comparisons he wishes to make, and prefer to draw conclusions only from the order of the magnitudes observed.

The analysis of such data is greatly facilitated by Table XX, which gives the average deviate of the  $r$ th largest of samples of  $n$  observations drawn from a normal distribution having unit variance. Symbolically this comes to

$$\mu_r = \int_{-\infty}^{\infty} \frac{n!}{(r-1)!(n-r)!} p^{n-r} q^{r-1} x z dx,$$

where  $z$  is the ordinate of the normal curve, and  $p$  and  $q$  are the probabilities respectively of falling short of and exceeding  $x$ .

From the order in which any subject places a series of objects scores may now be assigned. With a number of different subjects, the experimenter is then in a position to test, for example, whether the scores assigned to any one object significantly exceed those assigned to another; or, more generally, to apply an analysis of variance to determine whether the variance in score among objects exceeds the remainder due to differences in the order chosen by different subjects. More elaborate analyses afford tests of differentiation in preference between classes of subjects of different sex or age. The labour of summing the squares of individual scores is saved by using the sums of squares given in Table XXI.

The scoring of ties causes little difficulty. If, for example, the fifth and sixth objects out of 13 are judged to be equal, instead of scoring one .39 and the other .19, each is given the same score .29. In such cases the sum of squares needs adjustment. When only two objects are judged to be equal it is easy to see that the reduction is  $\frac{1}{2}(.39 - .19)^2 = .02$ , so that the sum of squares is 10.7904 in place of 10.8104 shown by the table.

TABLE XXII. THE LEADING DIFFERENCES OF POWERS OF NATURAL NUMBERS

The table gives values of  $\Delta^r o^s / r!$ , where  $\Delta^r o^s$  denotes the leading  $r$ th difference of the  $s$ th powers of the natural numbers commencing at zero. Its application to combinatorial problems arises from the identity.

$$\frac{\Delta^r o^s}{r!} = \sum_{s/r} \frac{s!}{(\rho_1)^{\pi_1} (\rho_2)^{\pi_2} \dots}$$

where  $(\rho_1^{\pi_1}, \rho_2^{\pi_2}, \dots)$  is a partition of the number  $s$  into  $r$  parts, i.e.

$$\sum \pi_i = s, \quad \sum \pi_i = r.$$

The partitional function on the right represents the number of ways of dividing  $s$  persons into the  $r$  parties specified by the partition. The summation proceeds over all partitions of  $s$  into  $r$  parts.

Hence  $\Delta^r o^s / r!$  is the number of ways of dividing  $s$  persons into  $r$  parties of all possible sizes. For example, with  $s = 4, r = 2$ , the table gives 7 ways, which are in fact,

$$(ab)(cd), (ac)(bd), (ad)(bc), (abc)(d), (abd)(c), (acd)(b), (bcd)(a).$$

If  $s$  objects are equally likely to fall into any of  $n$  classes, the probability that they will fall into exactly  $r$  of the possible  $n$  classes can be shown to be

$$\frac{1}{n^s} \frac{n!}{(n-r)!} \frac{\Delta^r o^s}{r!}$$

Hence the distribution of  $r$  can be derived from the table. Thus the table is useful for testing whether objects fall together in classes too often or too rarely. For practical applications see Stevens (12), (13).

### Example 9

In the expression for  $\pi$  it may be noticed that in the first 20 decimal places all digits save zero occur at least once. Zero is the only digit absent. It is not obvious how frequently 0, 1, 2, ... absent digits would be found in a series chosen at random.

Putting  $s = 20, n = 10, r = 9$  in the expression shown we find

$$\begin{aligned} & \frac{10!}{10^{20}} \times 1201 \cdot 13 \times 10^{10} \\ &= 3.6288 \times 120113 = .4359 \end{aligned}$$

Hence in 43.59 per cent. of trials we should expect exactly one absent digit; similarly we should expect no digit absent in 21.47 per cent. of such trials; consequently two or more digits will be absent in the remaining 34.94 per cent. The absence of one digit out of 10 is the commonest event in such trials.

The table may be extended by using the recurrence relation

$$\frac{\Delta^{r+1} o^{s+1}}{(r+1)!} = (r+1) \frac{\Delta^r o^s}{(r+1)!} + \frac{\Delta^r o^s}{r!}.$$

This equation may be written

$$\frac{r+1}{(r+1)!} \cdot \frac{o^{r+1}}{r!} = \frac{4^r (1+r)o^r}{r!} = \frac{4^r r^s}{r!}$$

showing that the entries derived from powers of natural numbers commencing at *unity*, may be read from this same table, with *r* and *s* both increased by one.

TABLE XXIII: ORTHOGONAL POLYNOMIALS

If a polynomial regression line

$$Y = a + bx + cx^2 + dx^3 + \dots$$

is to be fitted to a series of *n'* observations at equal intervals of *x*, we may conveniently fit instead the equivalent line

$$Y = A + B\xi_1 + C\xi_2 + D\xi_3 + \dots$$

where  $\xi_1, \xi_2, \xi_3, \dots$  are orthogonal polynomials of degree 1, 2, 3, ... ( $A = \bar{y}$  and  $\xi_1 = x - \bar{x}$ ). A method of determining the coefficients by successive addition, and also of calculating the polynomial values by the same process, is given in *Statistical Methods*. If the numerical values of the  $\xi$ 's (or multiples  $\xi' = \lambda \xi$  of them) are known for each value of *x* an alternative procedure (set out below) is available. Table XXIII shows these numerical values for all  $\xi'$  from  $\xi'_1$  to  $\xi'_5$ , and all *n'* from 3 to 52. In each case the smallest value of  $\lambda$  is chosen which gives integral values to  $\xi'$ . This value is shown at the foot of the corresponding column, and is the coefficient of the highest power of *x* in  $\xi'$ . The sum of squares of each set of  $\xi''$ 's is also shown. Above *n'* = 8 only the values for positive  $x - \bar{x}$  are given.

The coefficient of each  $\xi'$  in the regression equation is found by calculating the sum of the products of the observed values *y* and the corresponding values of  $\xi'$ , and dividing by the sum of squares of  $\xi'$ . Thus the coefficient of  $\xi'_2$  is

$$C' = \frac{S(y\xi'_2)}{S(\xi'^2_2)}$$

The corresponding sum of squares in the analysis of variance is

$$C'.S(y\xi'_2) = \frac{\{S(y\xi'_2)\}^2}{S(\xi'^2_2)}$$

and the estimated standard error of  $C'$  is  $s/\sqrt{S(\xi'^2_2)}$ .

If any or all of the values of *Y* corresponding to the *n'* observations are required they may be calculated directly from the values of the coefficients and the  $\xi''$ 's, using the equation

$$Y = A + B'\xi'_1 + C'\xi'_2 + D'\xi'_3 + \dots$$

This procedure is particularly useful when only a few values are required.

If the regression equation is required in terms of powers of *x* the formulæ for the  $\xi$ 's in terms of powers of *x* given in *Statistical Methods*, or the recurrence formula

$$\xi_{r+1} = \xi_1 \xi_r - \frac{r^2(n'^2-r^2)}{4(4r^2-1)} \xi_{r-1}$$

( $\xi_0 = 1$ ) may be used, together with  $\xi' = \lambda \xi$ . Alternatively the coefficients of the powers of *x* in each  $\xi'$  may be deduced from the tabulated values of the  $\xi$ 's, as illustrated in the example below (remembering that the even  $\xi$ 's contain only even powers of *x*, and the odd  $\xi$ 's odd powers of *x*).

The relative advantages of the above method and the alternative process of successive addition depend on the computing facilities available, but with a good multiplying machine, and no printing adding machine, the use of the  $\xi$ 's will be found to be decidedly more expeditious, especially when *n'* is small. If polynomials of the fourth or fifth degree are to be fitted the sums and differences of the pairs of observations (commencing from the centre) should be tabulated, thereby halving the number of multiplications. At the same time the values may frequently be reduced in magnitude by the deduction of a constant amount, and if necessary by rounding off. If polynomials have to be fitted to a number of sets of observations with the same *n'* it is worth tabulating  $\xi'_1 + \xi'_3 + \xi'_5$  and  $\xi'_2 + \xi'_4$ , and using the checks  $Sy(\xi'_1 + \xi'_3 + \xi'_5) = Sy\xi'_1 + Sy\xi'_3 + Sy\xi'_5$  and  $Sy(\xi'_2 + \xi'_4) = Sy\xi'_2 + Sy\xi'_4$ .

#### Example 10

Table 6 shows the yields (bushels per acre) of plots 9 and 7 of Broadbalk wheat field for the 30 years 1855-1884. The only difference in manurial treatment was that plot 9 received nitrate of soda and 7 an equivalent quantity of nitrogen as sulphate of ammonia. Investigate the slow changes in the difference between the two plots by fitting a polynomial of the fifth degree. (This example is discussed in *Statistical Methods*, Sections 26 and 28.1. The values there given have been rounded off to one decimal place.)

TABLE 6

Harvest Year.	9.	7.	9-7.	Harvest Year.	9.	7.	9-7.	Harvest Year.	9.	7.	9-7.
1855	29·6	33·0	-3·4	1865	44·1	40·2	+3·9	1875	30·5	26·6	+3·9
1856	32·4	36·9	-4·5	1866	32·5	29·9	+2·6	1876	33·3	25·5	+7·8
1857	43·8	44·8	-1·0	1867	29·1	22·2	+6·9	1877	40·1	19·1	+21·0
1858	37·6	38·9	-1·3	1868	47·8	39·2	+8·6	1878	37·2	32·2	+5·0
1859	30·0	34·7	-4·7	1869	39·0	28·2	+10·8	1879	21·9	17·2	+4·7
1860	32·6	27·7	+4·9	1870	45·5	41·4	+4·1	1880	34·1	34·3	-2
1861	33·8	34·9	-1·1	1871	34·4	22·3	+12·1	1881	35·4	26·1	+9·3
1862	43·4	35·9	+7·5	1872	40·7	29·1	+11·6	1882	31·8	34·8	-3·0
1863	55·6	53·7	+1·9	1873	35·8	22·8	+13·0	1883	43·4	36·3	+7·1
1864	51·1	45·8	+5·3	1874	38·2	39·6	-1·4	1884	40·4	37·8	+2·6

The computations are given in Table 7. The first step is to form the sums and differences of pairs of values, working outwards from the centre pair.

Thus

$$+14·9 = +4·1 + 10·8 \text{ and } -6·7 = +4·1 - 10·8.$$

The totals of the sums and the differences check against the sum and difference of the totals of the first fifteen and last fifteen of the original values. The total sum of squares of the deviations from the mean, 1016·99, can be calculated from the sums and differences, and, as a check, from the original values, at the same time as these totals are obtained.

	4·46					

The sums of products with the  $\xi'$  values are next calculated, and at the same time the regression coefficients and the sum of squares accounted for by each term. The sums of products may be checked by direct recalculation or by the method described above. Finally the analysis of variance can be completed, giving the residual mean square of 24·14. It will be seen the first two terms account for a substantial part

of the variation, but the mean squares of the remaining three terms are all below the residual mean square. Thus a parabola adequately describes the slow changes.

The equation of the parabola is

$$Y = 4.4667 + 0.13255 \xi'_1 - 0.029762 \xi'_2 \quad \dots \dots \dots \quad (1)$$

which can be converted into an equation in  $x$ , if this is required, by substitution for  $\xi'_1$  and  $\xi'_2$ . If  $x$  is measured from the centre point of the series  $\xi'_1 = 2x$  and  $\xi'_2 = \frac{3}{2}x^2 + C$ , the coefficients  $2$  and  $\frac{3}{2}$  of the highest powers of  $x$  being given in Table XXIII. Further, since  $\xi'_2 = -112$  when  $x = \pm \frac{1}{2}$ , we have immediately  $C = -112.375$ .

Alternatively the recurrence formula gives

$$\xi'_2 = \frac{3}{2}\xi'_3 = \frac{3}{2} \left[ \xi_1 \cdot \xi_1 - \frac{1^2 \cdot 899}{4 \cdot 3} \cdot 1 \right] = \frac{3}{2}x^2 - 112.375.$$

This gives the equation

$$Y = 7.8112 + 0.26510x - 0.044643x^2 \quad \dots \dots \dots \quad (2)$$

The value of  $Y$  for any given year can be calculated from (1). Thus for the year 1855

$$Y = 4.4667 + 0.13255 (-29) - 0.029762 (+203) = -5.4189.$$

Similarly for the year 1884, the value is  $+2.2690$ . Equation (2) will, of course, give the same values.

The parabola has a maximum at  $x = +2.969$ , i.e. at the date 1872.469,  $Y$  then having the value  $+8.2048$ . The improvement of plot 9 relative to plot 7 therefore appears to have reached a climax at about this date, there being some evidence of a reduction in the difference subsequently.

As a further exercise polynomials may be fitted to the yields of the two plots separately. The difference of these two polynomials clearly gives the polynomial already determined.

TABLE XXIV. CALCULATION OF INTEGRALS FROM EQUALLY SPACED ORDINATES

The table supplies data useful for the mechanical integration of functions calculated at not very closely spaced ordinates. Its use may be illustrated by the series of reciprocals of numbers from 15 to 19. In this case the integral is known to be  $\log_{10} 19/15$ , or  $0.23638,87780,66$ ; the average ordinate over the four units in the panel is, therefore,  $0.05909,71945,16$ . An accurate calculation can be obtained from the series of reciprocals and their even differences. Taking enough to use the eighth difference, these are as follows to ten places of decimals:—

Number.	Reciprocal.	Differences.			
		2nd.	4th.	6th.	8th.
13	0.07692,30769				
14	0.07142,85714	73.26008			
15	0.06666,66667	59.52380	3.23209		
16	0.06250,00000	49.01961	2.33426	28353	
17	0.05882,35294	40.84968	1.71996	18438	
18	0.05555,55556	34.39971	1.29004	12268	
19	0.05263,15789	29.23978	0.98280		
20	0.05000,00000	25.06265			
21	0.04761,90476				

Using the coefficients for 4 sub-panels in the table for central ordinate and even differences, the successive approximations obtained are as follows:—

	Correction.	Value.	Error.
No difference		0.05882,35294,00	-27.36651,16
2nd ,	+27.23312,00	0.05909,58606,00	-13339,16
4th ,	+13377,47	0.05909,71983,47	+38,31
6th ,	-39,02	0.05909,71944,45	-71
8th ,	+86	0.05909,71945,31	+15

To show the adequacy of the adjustments two additional figures have been retained. The evaluation is satisfactory using only 6th differences, although the 8th difference is a four-figure number.

The formulæ using integral multipliers in the first part of the table (4 sub-panels) give exactly equivalent values to the use of 4th and 6th differences.

#### TABLES XXV TO XXXII AND XXXIV. LOGARITHMS, TRIGONOMETRICAL FUNCTIONS, ETC.

These tables comprise the standard functions that are likely to be required by the statistician. Five-figure accuracy has been adopted in most of the tables, since four-figure tables are already sufficiently plentiful, and five figures bridge the gap between the slide-rule (roughly three-figure accuracy) and seven-figure standard tables.

In addition to the ordinary table of logarithms to base 10 of numbers 1.00 to 9.99 (Table XXV) four pages of natural logarithms ( $\log_e 1.00 - \log_e 99.9$ ) are included (Table XXVI). This table will prove useful to those who find it convenient to work with natural logarithms. Exact squares of all three-figure numbers (Table XXVII) will enable an occasional analysis of variance to be performed without a machine. Square roots (Table XXVIII) are so tabulated that the square roots of each three-figure number and of ten times that number appear together. This facilitates reference to the table, and serves as a reminder of the necessity of considering the position of the decimal point before taking out a square root. Reciprocals (Table XXIX) are given to six figures, since interpolation is not likely to be required in this table when a machine is available, and the additional figure is useful when division is being performed on a machine by means of reciprocals.

Table XXX gives the factorials of the numbers 1-300 to six significant figures, and their logarithms to seven decimal places. Of the trigonometrical functions only natural sines (Table XXXI) and tangents (Table XXXII) have been included. By tabulating  $(90^\circ - \theta) \tan \theta$  instead of  $\tan \theta$  for values of  $\theta$  greater than  $60^\circ$  five-figure accuracy of interpolated values is assured, even for high angles.

In Table XXXIV will be found a collection of constants, conversion factors, etc. Only the English, American and metric systems of weights and measures have been included, the more uncommon measures of these systems being given in their most easily remembered forms.

The tabulation of the above tables to 5 and 6 figure accuracy does not preclude their use to four-figure accuracy only when the circumstances warrant it. For this purpose they will be found little slower than the ordinary four-figure tables, since the amount of page turning is the same. When using logarithms to four-figure accuracy it will frequently be found most expeditious, as well as slightly more accurate, to retain 5 figures in the logarithmic calculations, without making any attempt to interpolate to more than four-figure accuracy. General instructions for interpolation are given in the last section of the Introduction.

#### TABLE XXXIII. RANDOM NUMBERS

This table contains 750 two-figure random numbers arranged on six pages. The method of construction of the table, and the tests made on it, are described in the first edition. Methods of using the table may best be made clear by a couple of examples.

*Example 11.* Required to select a series of numbers at random from the numbers 1-16.

The simplest way of doing this is to select a row, column or diagonal of two-figure numbers (such selection being made without previous inspection of the numbers themselves), and pick out all numbers between 1 and 16 as they occur. With a number like 16, however, such a procedure is tedious and wasteful of numbers. As an alternative we may divide each two-figure number by 16 and take the remainder (or counting as 16). It is clear that to give all numbers an equal chance of selection the numbers 97, 98, 99 and 00 must be rejected. A modification of this process, which somewhat lightens the arithmetic, is to use the divisor 20 instead of 16, rejecting any number which gives 00, 17, 18 or 19. Thus 73 would be read as 13.

*Example 12.* Required to arrange 16 treatments, numbered 1-16, in random order.

We may start by selecting a series of numbers between 1 and 16 by one of the methods of the last example, rejecting any number if it occurs a second time. After half the numbers have been selected, however, the process becomes tedious, since the rejections become more numerous, on the average, than the selections. This difficulty may be overcome by choosing the first number by making a selection between 1 and 16, the second by making a selection between 1 and 15, the third by making a selection between 1 and 14, and so on, the actual number selected at each stage being taken to indicate (by counting from one end of the series) which of the numbers still remaining is to be chosen. This operation can easily be performed by writing down all the numbers (or other symbols) in order and striking out each as it is selected. Thus, taking the fourteenth column of two-figure numbers on page IV, which reads

82, 05, 30, 58, 55, 66, 53, 16, 89, 56, 16, 70, 70, 07, 37,

We obtain on dividing successively by 16, 15, 14, 13 . . . the following series of remainders

$$2, 5, 2, 6, 7, 11, 3, 7, 1, 7, 4, 5, 2, 1, 1.$$

We therefore select the second, fifth, second, etc., numbers of all numbers still unselected. This gives

$$2, 6, 3, 9, 11, 16, 5, 13, 1, 15, 10, 14, 7, 4, 8, 12.$$

Various combinations of the above methods can also be used. An excellent way of proceeding in Example 12 is to select the first 7 treatments by selecting a number between 1 and 16 by dividing by 20, as suggested in Example 11, rejecting any number which occurs a second time, afterwards completing the selection by division of the subsequent two-figure numbers by decreasing divisors according to the method just given. Using this process on the numbers printed above we obtain as the first 7 treatments

$$2, 5, 10, 18 \text{ (rejected), } 15, 6, 13, 16.$$

Division of the subsequent numbers by 9, 8, 7, etc., gives the series 8, 8, 2, etc., so that the corresponding treatments are the eighth, eighth, second, etc., of those remaining, i.e. 12, 14, 3, etc.

### INTERPOLATION

Many of the tables are provided with special aids to rapid interpolation, such as proportional parts, mean differences, and tabular differences printed in the tables. In other cases linear interpolation is generally sufficient. Thus if the table gives values for  $u_x$  and  $u_{x+1}$ , and the value is required for  $u_{x+\theta}$ , we may take

$$u' = \theta u_{x+1} + \phi u_x,$$

where  $\phi$  stands for  $1-\theta$ . This form is convenient for machine work; mentally it is often quicker to use the differences between the tabular values and calculate

$$u' = u_x + \theta(u_{x+1} - u_x).$$

Modern work, especially that of Jordan (20) and Aitken (18), (19), has much facilitated the use of interpolation, without the aid of differences, in cases for which linear interpolation is thought not to be sufficiently accurate. A very useful improvement on the linear interpolate, based on four instead of two adjacent tabular values, is obtained by supplementing the linear interpolate from the two nearest entries by that from the next two which enclose them. This latter is

$$u'' = \frac{1}{3}\{(1+\theta)u_{x+2} + (1+\phi)u_{x-1}\}.$$

Curvature of the entries is shown by  $u'$  differing from  $u''$ , the error of the former being generally of the same sign as that of the latter, though smaller. To complete the adjustment calculate the product  $\theta\phi$ , and use

$$u = \frac{1}{2}\{(2+\theta\phi)u' - \theta\phi u''\}$$

which is the correct 4-point interpolate, obtained without the use of differences.

In the tables in which mean proportional parts are given for each line of the table, only the proportional parts for 1 to 5 units are included, instead of, as is customary in tables of this type, for 1 to 9 units, it being intended that subtraction from the next higher tabular value should be used when interpolating for fractions above 0.5. The exact procedure will be clear from the examples below. The advantages of this innovation are two-fold: firstly the differences which have to be dealt with are smaller, thus facilitating the arithmetic (which should be done mentally), and secondly the errors arising from the use of *mean* proportional parts for the whole of each line are reduced.

The actual tables in which this type of arrangement has been adopted, for the whole or the greater part of the table, comprise: II (ordinates of the normal distribution), IX (probits), XXV and XXVI (logarithms), XXVIII (square roots), XXXI (sines), and XXXII (tangents). In tables XXV and XXVI (logarithms) the common practice is followed of tabulating the values for the numbers 10-19 on 20 lines instead of 10, so that five values instead of ten occur on each line, thus reducing the range covered by each set of mean proportional parts (which are here changing rather rapidly) to five units of the interval of tabulation.

In Table XXIX (reciprocals) mean differences of consecutive tabular values, instead of mean proportional parts, are given for each line of the table (thus allowing space for the tabulation of six figures instead of five). These mean differences correspond to ten times the mean proportional parts for 1 unit given in the other tables. This course has also been followed for Table VII (transformation of  $r$  to  $z$ ).

In those parts of Table XI (probits) and Table XXIX (reciprocals) where the first differences are changing so rapidly that the mean proportional parts or mean differences are too inaccurate to be of value, the actual first differences between each tabular value and the next are given.

In Table XXVII (squares) no differences are given. Squares of four-figure numbers may be easily derived by the use of the expansion of  $(a+b)^2$ , as indicated in the note below the table.

In all the above tables, except the last two lines of the table of probits and the first 20 lines (1.0-2.9) of the table of reciprocals, linear interpolation will give results accurate to one unit in the last tabulated place. The

use of mean proportional parts or mean differences will, of course, give errors greater than this in those parts of the tables where the differences are changing rapidly. The actual magnitude of the error may be assessed by seeing how rapidly the proportional parts are changing from line to line, as illustrated in example 13 below. The mean proportional parts should therefore be used with discretion when full tabular accuracy is required.

#### Example 13

Find the natural logarithm of 11.06. We have  $\log_{e} 11.1 = 2.40695$ . The proportional part for 4 is 357. Thus  $\log_{e} 11.06 = 2.40338$ . The true value = 2.40333.5, the discrepancy being due to the use of the mean proportional part instead of the correct proportional part, which is 0.4 ( $2.40695 - 2.39790$ ), i.e. 362. As will be seen by inspection the proportional parts are here changing rather rapidly. A closer approximation would have been obtained by taking this change into account, interpolating roughly in the required column of proportional parts, i.e. between 357 and 374.

#### Example 14

Find the square root of 29.426. The square root of 29.4 is 5.4222, and since  $2.6 = 3 - 0.4$  the required proportional part is 28-3.7 or 24, giving the value 5.4246. (True value = 5.42457.)

#### Example 15

Find the angle whose tangent is 0.79134. The nearest tabular value, 0.79259, is that for  $38^{\circ} 24'$ . The difference is -125. To the nearest minute, therefore, the angle is  $38^{\circ} 21'$ , a closer approximation being  $38^{\circ} 21.4'$ . (True value =  $38^{\circ} 21.36'$ .)

#### Example 16

Find the angle whose tangent is 2.82. Ordinary inverse interpolation is here impossible, since  $(90^{\circ} - \theta)$   $\tan \theta$  is tabulated, but any approximation may be rapidly improved by dividing the tabular value by the given tangent, and subtracting from  $90^{\circ}$ . First find a rough approximation by interpolation in the auxiliary marginal table of tangents. This gives a value between  $70^{\circ} 4^{\circ}$  and  $70^{\circ} 5^{\circ}$ , i.e. between  $70^{\circ} 24'$  and  $70^{\circ} 30'$ . We then obtain

Angle.	Tabular Value (x).	$x/2.82$ .	Plus Original Angle.
$70^{\circ} 4$	55.043	19.5188	89.9188
$70^{\circ} 5$	55.066	19.5270	90.0270

The second column gives the tabular values from the table, the third is the result of dividing these by the given tangent 2.82. Subtracting either of these from  $90^{\circ}$  gives a better approximation. For full accuracy we use the fourth column, which is the sum of these quotients and the original angles. Inverse linear interpolation between the last two values for the value 90 will now give the required angle, namely  $70^{\circ} 47.50$ , i.e.  $70^{\circ} 28.50'$ . (True value =  $70^{\circ} 28.499'$ .)

#### ADDENDUM

TABLE VIII.

The values tabulated for "15 and over" are correct for 15; they differ appreciably from the limiting value for  $a \rightarrow \infty$ , i.e.  $p + \frac{1}{3}(x^2+2)(1-2p)$ , for "a or fewer", and its complement,  $1-p - \frac{1}{3}(x^2+2)(1-2p)$ , for "a or more". Here  $x$  is the normal deviate appropriate to the level of significance chosen; for example  $x=1.96$  at  $P=0.025$ . The values tabulated, however, are adequate for large samples when full accuracy in the expectation is not required.

P	.	.	·001	·000,1	·000,01	·000,001	·000,000,1	·000,000,01	·000,000,001	
x	.	.	3·29053	3·89059	4·41717	4·89164	5·32672	5·73073	6·10941	

The value of P for each entry is found by adding the column heading to the value in the left-hand margin. The corresponding value of  $x$  is the deviation such that the probability of an observation falling outside the range from  $-x$  to  $+x$  is P. For example, P = ·03 for  $x = 2·170090$ ; so that 3 per cent. of normally distributed values will have positive or negative deviations exceeding the standard deviation in the ratio 2·170090 at least.

The table of probits (Table IX) provides a more extensive (P, x) table. The probit table refers to a single tail of the distribution, and the P's derived from that table must therefore be multiplied by 2 to bring them into line with the P's of Table I.

For larger values of  $n$ , the expression  $\sqrt{2\chi^2} - \sqrt{2n-1}$  may be used as a normal deviate with unit variance, remembering that the probability for  $\chi^2$  corresponds with that of a single tail of the normal curve.

For high values of  $n_1$  and  $n_2$ ,  $z$  (20 per cent.) =  $\frac{0.8416}{\sqrt{h-0.6}} - 0.4514 \left( \frac{1}{n_1} - \frac{1}{n_2} \right)$  approximately,

where  $\frac{2}{h} = \frac{1}{n_1} + \frac{1}{n_2}$ . In other parts of the table interpolation is approximately linear if reciprocals of  $n_1$  and  $n_2$  are taken.

For high values of  $n_1$  and  $n_2$ ,  $z$  (5 per cent.) =  $\frac{1.6449}{\sqrt{h-1}} - 0.7843 \left( \frac{1}{n_1} - \frac{1}{n_2} \right)$  approximately,  
where  $\frac{2}{h} = \frac{1}{n_1} + \frac{1}{n_2}$ . In other parts of the table interpolation is approximately linear if reciprocals of  $n_1$  and  $n_2$  are taken.

TABLE VIII. TESTS OF SIGNIFICANCE FOR  $2 \times 2$  CONTINGENCY TABLES

Calculate  $\chi_c$ , the square root of  $\chi^2$  corrected for continuity (Fisher, *Statistical Methods*, 21.01). Determine  $m =$  the smallest expectation of any class, and  $p = \frac{\text{the smallest expectation}}{\text{the smallest marginal total}}$

The table gives the 2.5 and 0.5 per cent. points of  $\chi_c$  for each tail separately, these being different for the two tails except when  $p = 0.5$ . The observed set of values will lie on the longer tail if the observed number in the cell with smallest expectation is greater than expectation.

Since three of the four marginal totals are independent their values are not completely determined by  $m$  and  $p$ . For a given  $m$  and  $p$  there is a whole set of contingency distributions, and a corresponding set of values of  $\chi_c$  for each level of significance. The variation of these  $\chi_c$  is, however, small. The table gives the greatest and least values, i.e. those for the binomial distribution (Roman type), and the limiting contingency distribution (black type). When  $p = 0$  there is only one value, this being derived from the Poisson distribution.

The table should always be used in place of the ordinary  $\chi^2$  table when  $m$  is less than 10. Even with values of  $m$  as great as 100 the gain in precision is appreciable when  $p$  is small and the interest centres in the probability of a single tail (i.e. deviations in one direction only). The correction for continuity should be used when  $m$  is less than 500.

In regions of the table where no values are given, and to determine the exact probability in doubtful cases, the exact solution (on which this table is based) must be used (Fisher, *Statistical Methods*, 21.02).

The table can be used for testing the deviation of a sample of a binomial distribution with known  $p$ . Remember to include the contributions to  $\chi^2$  from both classes when calculating  $\chi_c$ .

Notes on Tables VI and VII.

For a total correlation,  $n$  is 2 less than the number of pairs in the sample; for a partial correlation, the number of eliminated variates also should be subtracted. The probability given at the head of each column of Table VI represents the chance that  $r$  will be greater than the values given or less than minus these values.

Table VII gives the transformation  $r = (e^{2z} - 1)/(e^{2z} + 1)$  or  $z = \frac{1}{2} \{\log_e(1+r) - \log_e(1-r)\}$ . With  $n$  defined as above  $z$  is distributed approximately normally with variance  $1/(n-1)$ . For exact work correct for bias in  $z$  by subtracting  $r/2(n+1)$  from  $z$ .

The table is also sometimes useful for transforming the probability scale, being equivalent to  $z = \frac{1}{2} \{\log p - \log(1-p)\}$  where  $r = 2p-1$ . (See Introduction).

TABLE VIII. BINOMIAL AND POISSON DISTRIBUTIONS: LIMITS OF THE EXPECTATION

To obtain the limits of the probability of an event (observed to occur  $a$  times out of  $N$ ) corresponding to a given probability level  $P$ , divide the tabulated values by  $N$ , first interpolating if necessary by linear interpolation with reference to  $p = a/N$ . The limits of the expectation of Poisson distributions are given directly, taking  $p = 0$ . For  $a > \frac{1}{2}N$  enter the table with  $a' = N - a$ . For 15 and over add the tabulated corrections to the limits of the expectation calculated from the standard error  $\sqrt{\{a(1-p)\}}$ .

When  $x > 1$  and  $y > 2$  enter the table with the decimal part of  $x$  or  $y$  only.

Calculate the mean fertile level,  $x = \text{number of fertile plates}/\text{number of cultures at each level } n$ , and the mean sterile level,  $y = \text{number of levels} - x$ . Enter the table with  $x$  or  $y$ , as indicated, and determine the corresponding value of the tabular entry  $K$ . When  $x$  and  $y$  fall outside the tabulated range use the value marked with an asterisk (\*). The estimate of the number,  $\lambda$ , of organisms in the quantity of the medium used for one culture at the highest concentration is then given by  $\log \lambda = x \log a - K$ , where  $a$  is the dilution factor. The average value of the variance of the mean fertile level is  $\frac{1}{n} \log^2 a$ , and the average value of the variance of  $\log \lambda$  is  $\frac{1}{n} \log^2 a \log a$  (see Introduction). Thus:

Two-fold

$$\begin{aligned}\log \lambda &= 0.30103 x - K \\ \overline{V(x)} &= 1/n \\ \overline{V(\log \lambda)} &= 0.091/n\end{aligned}$$

Four-fold

$$\begin{aligned}\log \lambda &= 0.60206 x - K \\ \overline{V(x)} &= 1/2n \\ \overline{V(\log \lambda)} &= 0.201/n\end{aligned}$$

Ten-fold

$$\begin{aligned}\log \lambda &= x - K \\ \overline{V(x)} &= 0.301/n\end{aligned}$$

TABLE IX. PROBITS

Transformation of the Sigmoid Dosage Mortality Curve to a Straight Line. (C. I. Bliss.)

For more detail see  
values for 95-100.

The probit corresponding to a given percentage is the normal deviate (increased by 5 to avoid negative values) exceeded by this percentage of the population (see Table I).

Many fractions with higher denominators may be quickly obtained by simple interpolation between adjacent values, e.g. from 5/13 and 7/18, because  $\frac{5+7}{13+18} = \frac{12}{31}$ , the deviate for 12/31 is judged to be  $0.2868 + \frac{13}{31} (0.0112) = 0.2868,97$ .

True value 0.2868,94. Each thirtieth is marked by an asterisk.

To convert to probit values subtract from 5, and for fractions  $\lambda$  greater than  $\frac{1}{2}$  add the value for  $1-\lambda$  to 5.

In toxicology the probit values used are found by adding 5 to a normal deviate. The weighting coefficient for any test,  $Z^2/PQ$ , is derived from the probit,  $Y$ , given by some provisional formula. The appropriate score for tests in which all animals die is  $Y+Q/Z$ .

For refined adjustments, even if an empirical probit is available, the test may be accurately scored as  $y_e = Y+Q/Z-q/Z$  where  $q$  is the observed proportion surviving.

Thus, if  $Y = 5.3$ , in a test in which three survive out of 12, we may take for the adjusted score

$$6.3018 - \frac{3}{12} (2.6220) = 5.6463$$

in place of the empirical probit 5.6745 derived from the fraction,  $\frac{1}{4}$ , surviving.

### ANGULAR TRANSFORMATION

90	71.6	72.5	73.6	74.7	75.8	77.1	78.5	80.0	81.9	84.3

In connection with an observed fraction  $p$ , it is often advisable to use the angular value  $\phi$ , such that  $p = \sin^2 \phi$ .  $\phi$  rises to  $90^\circ$  at 100 per cent. The amount of information supplied by  $n$  observations about  $\phi$ , in circular measure, is  $4n$ , or in degrees,  $\frac{4\pi^2 n}{180^2} = \frac{\pi^2 n}{8100}$ . Consequently in large samples, the variance of  $\phi$ , as estimated from a sample, is  $\frac{8100}{\pi^2 n} = \frac{820.7}{n}$  independently of the true value of  $\phi$ .

For small angles use  $57.3\sqrt{p}$  in preference to interpolation.

1/11	17.5	5/28	25.0	7/26	31.3	9/25	36.9	4/9	41.8		
2/21	18.0	2/11	25.2	3/11	31.5	4/11	37.1	13/29	42.0		

For fractions exceeding  $\frac{1}{2}$ , subtract the fraction from 1, and the angle from  $90^\circ$ . Each thirtieth is marked by an asterisk; for interpolation see Table X.

TABLE XIV. ANGULAR TRANSFORMATION  
Angular Values for Adjustments of Special Accuracy

Expected angular value $\phi$ .	Maximal working angle $\phi + \frac{1}{2} \cot \phi$ .	Range cosec $2\phi$ .	Expected angular value $\phi$ .	Maximal working angle $\phi + \frac{1}{2} \cot \phi$ .	Range cosec $2\phi$ .	Expected angular value $\phi$ .	Maximal working angle $\phi + \frac{1}{2} \cot \phi$ .	Range cosec $2\phi$ .
45	73.6	57.3	60	76.5	66.2	75	82.7	114.6
46	73.7	57.3	61	76.9	67.6	76	83.1	122.0
47	73.7	57.4	62	77.2	69.1	77	83.6	130.7
48	73.8	57.6	63	77.6	70.8	78	84.1	140.9
49	73.9	57.9	64	78.0	72.7	79	84.6	152.9
50	74.0	58.3	65	78.4	74.8	80	85.1	167.5
51	74.2	58.6	66	78.8	77.1	81	85.5	185.4
52	74.4	59.0	67	79.2	79.7	82	86.0	207.9
53	74.6	59.6	68	79.6	82.5	83	86.5	236.8
54	74.8	60.2	69	80.0	85.6	84	87.0	275.6
55	75.1	61.0	70	80.4	89.1	85	87.5	330.0
56	75.3	61.8	71	80.9	93.1	86	88.0	411.7
57	75.6	62.7	72	81.3	97.5	87	88.5	548.1
58	75.9	63.7	73	81.8	102.5	88	89.0	821.4
59	76.2	64.9	74	82.2	108.1	89	89.5	1641.7

This table supplies for the angular transformation the same facilities as does Table XI for probits. The weighting coefficient,  $1/820.7$ , is constant for all angular values, and is only needed in testing homogeneity. The adjusted score for expected angular value  $\phi$ , is  $\phi_e = \phi + \frac{1}{2} \cot \phi - q \operatorname{cosec} 2\phi$  where  $q$  is the observed proportion surviving.

For values less than  $45^\circ$  subtract from  $90^\circ$ ; the range is then as tabled; its lower extremity is at  $90^\circ$  less the value in the table.

When constructing squares for use in experimental arrangements use the randomization procedure described in the Introduction.

TABLE XV. LATIN SQUARES—continued

## The 6×6 Latin Squares

Five conjugate pairs of transformation sets, and twelve sets containing conjugates. The numbers above the squares indicate the number in each set, *s* standing for self-conjugate and *c* for conjugate. Each pair of conjugate sets can be turned into the following transformation set by interchanging rows or columns with letters.

14								.04	.09	.12
15										.04

Tests of psychological preference and some other experimental data suffice to place a series of magnitudes in order of preference, without supplying metrical values. Analyses of variance, correlations, etc., can be carried out on such data by using the normal scores, appropriate to each position in order, in a sample of the size observed. Ties may be scored with the means of the ordinal values involved, but in such cases the sums of squares given in Table XXI will require correction.

TABLE XXI. SUMS OF SQUARES OF MEAN DEVIATIONS TABULATED

TABLE XXII. INITIAL DIFFERENCES OF POWERS OF NATURAL NUMBERS

These values, the so-called "differences of zero," enter into many combinatorial formulæ, as in Whitworth's *Choices and Chance*. They afford exact solutions of some important sampling problems (Stevens, (12), (13), 1937). In particular if  $s$  objects are distributed among  $n$  classes, the probabilities of any one object falling into each class being equal, the distribution of  $r$ , the number of occupied classes, is

$$\frac{1}{n^s} \frac{n!}{(n-r)!r!} D^r \alpha^s$$

The values tabulated,  $D^r \alpha^s / r!$ , are the  $s$ th differences of powers of natural numbers, advancing from  $\alpha^s$ , divided by  $r!$ , for values of  $s$  from 2 to 25.

TABLE XXIV. CALCULATION OF INTEGRALS FROM EQUALLY SPACED ORDINATES

Each panel over which the integral is required is divided by calculated ordinates into a number of sub-panels, usually an even number, and often a power of 2. The formula may involve only internal and terminal ordinates, or also adjacent external ordinates. Ordinates equidistant from the centre have equal coefficients. The central coefficient is the last given.

Number of sub-panels.	No external ordinates. Coefficients.	Divisor.	One external ordinate. Coefficients.	Divisor.
2	1, 4	6	-1, 34, 114	180
4	7, 32, 12	90	-4, 171, 612, 332	1890
6	41, 216, 27, 272	840	-9, 482, 1908, 774, 2090	8400

Equally we may use the central ordinate and its even differences with the following coefficients:

Number of sub-panels.	$\delta^0$	$\delta^2$	$\delta^4$	$\delta^6$	$\delta^8$	$\delta^{10}$			
2	1	0.16	-0.05	0.00066	1375	-0.00010	141	0.00001	76
4	1	0.66	0.77	-0.00211	6402	0.00022	928	-0.00003	31
6	1	1.50	1.550	0.04880	9523	-0.00107	143	0.00010	28
8	1	2.66	1.911	-0.48677	2486	0.3488	536	-0.00063	28
10	1	4.16	4.861	2.27843	9153	-0.44587	743	0.2683	41

When the number of sub-panels is large, Gregory's formula, in terms of terminal differences, is valuable:

$$\int_0^x f(x)dx = (\frac{1}{2}f_0 + f_1 + f_2 + \dots + f_{r-1} + \frac{1}{2}f_r) - a_1(4f_{r-1} - 4f_0) - a_2(4^2f_{r-2} + 4^2f_0) - a_3(4^3f_{r-3} - 4^3f_0) - a_4(4^4f_{r-4} + 4^4f_0) \dots$$

where  $a_r$  is the coefficient of  $x^r$  in the expansion of  $-1/\log(1-x)$ .

Values of  $a_1$  to  $a_{16}$

1	0.08333	5	0.01426	91799	9	0.00678	585	13	0.00421	5

9.9	•101010	100908	100806	100705	100604	100503	100402	100301	100200	100100	-101

Thus  $1/4.214 = 0.237530 - 0.000222 = 0.237308$ , since  $0.4 \times 555 = 222$  (correct value 0.237304).

The power of 10 by which to multiply the factorial is given by the whole number of the logarithm.

TABLE XXX. FACTORIALS—*continued*

No.	Factorial.	Logarithm.	No.	Factorial.	Logarithm.	No.	Factorial.	Logarithm.

TABLE XXXIV. CONSTANTS, WEIGHTS AND MEASURES, ETC.

*Mathematical Constants*

$\pi = 3.14159 26535 89793 23846$	$e = 2.71828 18284 59045 23536$	$\gamma = 0.57721 56649 01532 86061$
$\log_{10}\pi = 0.49714 98726 94133 85435$	$\log_{10}e = 0.43429 44819 03251 82765$	$e^\gamma = 1.78107 24179 90197 98522$
$1/\sqrt{2\pi} = 0.39894 22804 01432 67794$	$\log_{10} = 2.30258 50929 94045 68402$	$e^{-\gamma} = 0.56145 94835 66885 16983$

*Physical Constants*

Velocity of light =  $3.00 \times 10^{10}$  cm./sec. = 186,000 miles/sec. The first number is the ratio of electromagnetic to electrostatic unit of charge.

Ionic (electronic) charge ( $e$ ) =  $4.77 \times 10^{-10}$  E.S.U. =  $1.59 \times 10^{-20}$  E.M.U. Mass of electron ( $m_0$ ) =  $9.00 \times 10^{-28}$  g.

Planck's constant ( $h$ ) =  $6.55 \times 10^{-27}$  erg secs.

Energy of gas molecule per  $1^{\circ}$  C. absolute =  $2.06 \times 10^{-16}$  ergs.

Number of molecules in 1 gm. molecule of gas =  $6.06 \times 10^{23}$ .

Electrical charge of 1 gm. equivalent in electrolysis (Faraday) =  $9.65 \times 10^3$  E.M.U.

Gas constant ( $R$ ) =  $8.315 \times 10^7$  c.g.s. ( $pV = RT \times$  mass in gram molecules).

Constant of gravitation ( $G$ ) =  $6.67 \times 10^{-8}$  c.g.s. ( $f = Gmm'/r^2$ ).

Acceleration due to gravity ( $g$ ). Teddington ( $N. 51^{\circ} 28.1'$ ):  $981.181$  cm./sec. $^2$  =  $32.191$  ft./sec. $^2$ ; Washington ( $38^{\circ} 56.5'$ ):  $980.082$ ; whence at lat.  $\lambda$ , height  $H$  m.:  $980.618 - 2.586 \cos 2\lambda + 0.03 \cos 4\lambda - 0.0003086 H$ .

The earth. Equatorial radius = 3963.4 miles, polar radius = 3950.0 miles.  $1^{\circ}$  of Latitude = 68.70 mls. (equator), 69.41 mls. (pole). Mean density = 345 lb./ft. $^3$  = 5.517 g./cm. $^3$

Distance of sun =  $93 \times 10^6$  miles. Distance of moon = 239,000 miles.

Solar radiation (Washington, D.C.) = 0.35 cal./cm. $^2$ /sec.

Velocity of sound ( $6^{\circ}$  C.) =  $3.35 \times 10^4$  cm./sec. = 1100 ft./sec. Audible sound  $\rightarrow$  Lower limit, 30 vibr./sec.; upper limit, 24,000-41,000 vibr./sec. Middle C of piano, 261 vibr./sec. Wave-lengths of visible light: 4 to  $7 \times 10^{-5}$  cm.

Temperature	Centigrade	-40	-30	-20	-10	0	10	20	30	40	50	100	$1^{\circ}$ F. = $\frac{5}{9}$ C.
Equivalents	Fahrenheit	-40	-22	-4	14	32	50	68	86	104	122	212	Absolute zero of temperature =
	Réaumur	-32	-24	-16	-8	0	8	16	24	32	40	80	-273.1° C.

*Mechanical and Electrical Units*

*Force.*  $g$  dynes = 1 gm. weight,  $g$  poundals = 1 lb. weight, where  $g$  is acceleration due to gravity measured in appropriate units (cm./sec. $^2$  or ft./sec. $^2$ ). 1 poundal =  $1.3825 \times 10^4$  dynes.

*Pressure.* 1 atmosphere = 760 mm. (29.921 ins.) of mercury ( $0^{\circ}$  C., Lat.  $45^{\circ}$ ) = 33.899 ft. of water ( $4^{\circ}$  C.) =  $14.696$  lb./in. $^2$  =  $1.01325 \times 10^6$  dynes/cm. $^2$  1 bar =  $10^6$  dynes/cm. $^2$  = 0.98692 atmos. 1 lb./in. $^2$  =  $70.307$  ( $1.014223$ ) gm./cm. $^2$

*Work, Power, etc.* 1 erg = 1 dyne cm. 1 joule =  $10^7$  ergs = 1 watt second. 1 foot pound =  $1.356 \times 10^7$  ergs. 1 horse power (H.P.) = 550 ft. lb. per sec. = 746 watts (continental H.P. = 736 watts). 1 calorie = heat to raise 1 gm. of water  $1^{\circ}$  C. at a specified temperature.  $1.15^{\circ}$  C. calorie = 1 mean calorie ( $0^{\circ}$  C.- $100^{\circ}$  C.) =  $4.185 \times 10^7$  ergs. 1 British Thermal Unit (1 lb. water  $\times 1^{\circ}$  F.) = 252.0 calories =  $2.930 \times 10^{-4}$  kilowatt hours =  $3.929 \times 10^{-4}$  horse power hours =  $10^{-5}$  gas therms. 1 Board of Trade Unit = 1 kilowatt hour.

*Electrical.* Relations between engineering units and electromagnetic units. Charge: coulomb =  $10^{-1}$  E.M.U. Current: ampere =  $10^{-1}$  E.M.U. Potential: volt =  $10^8$  E.M.U. Resistance: ohm =  $10^9$  E.M.U. Capacity: farad =  $10^{-9}$  E.M.U. Inductance: henry =  $10^9$  E.M.U. Flux: maxwell =  $10^9$  E.M.U. Magnetic force: gauss =  $10^9$  E.M.U.

*Supposed Duration of Geologic Periods (E. W. Barnes)*

	Duration Million Years.		Duration Million Years.
Pleistocene		Permian	
Tertiary or Cainozoic era		Carboniferous	
Pliocene	60	Devonian	175

Unit density = 1 g. per cu. cm. = .036128 lb. per cu. in.

*Equation of Time*

Jan. 1 + 3m. 11s.	Mar. 1 + 12m. 34s.	May 1 - 2m. 57s.	July 1 + 3m. 32s.	Sept. 16 - 5m. 6s.	Nov. 16 - 15m. 10s.
," 16 + 9 33	," 16 + 8 51	," 14 - 3 49*	," 26 + 6 18*	Oct. 1 - 10 16	Dec. 1 - 10 56
Feb. 1 + 13 37	Apr. 1 + 4 1	June 1 - 2 27	Aug. 16 + 4 11	," 16 - 14 20	," 12 - 6 15
," 12 + 14 25*	," 16 0 0	," 15 0 0	Sept. 1 0 0	Nov. 3 - 16 21*	," 25 0 0

When positive add the equation of time to apparent solar time to obtain mean solar time. The values given are mean values. Maxima and minima are marked with asterisks. 1 sidereal day = 23 h. 56 m. 4.09 s.

*Saturated Vapour Pressure of Water (Millibars)*

°C.	-50	-40	-30	-20	-10	-5	-2	40	73.76
Ice	.039	.129	.381	1.035	2.600	4.017	5.173	50	123.3
Water	—	—	—	1.270	2.865	4.217	5.274	60	199.2
°C.	0	1	2	3	4	5	6	7	80
0	6.105	6.567	7.058	7.579	8.134	8.723	9.350	10.02	473.4
10	12.28	13.12	14.02	14.97	15.98	17.05	18.18	19.37	701.0
20	23.38	24.86	26.43	28.09	29.83	31.67	33.61	35.65	1013.2
30	42.43	44.92	47.55	50.31	53.19	56.23	59.41	62.75	15544

Critical temperature: 374°. Critical pressure: 220.6 bars. Interpolate logarithmically.

*Composition of Fertilizers (Commercial Grades on the English Market)*

	%N		%K <sub>2</sub> O		%P <sub>2</sub> O <sub>5</sub>
Sulphate of ammonia	20.6	Sulphate of potash	48	Superphosphate	14-16 water soluble
Nitrate of soda	15½	Muriate of potash	50	Basic slag	14-18 total
Nitro chalk	15½	Potash salts	20, 30	Rock phosphate	26-28
Calcium cyanamide	20.6	Kainit	14		

Many of these fertilizers are mixtures of two or more constituents in naturally occurring or conventional proportions. Pre-war values are given.

## English Weights and Measures

### *Length*

1 foot = 12 ins. 1 yard = 3 ft.  
1 mile = 1760 yds. = 5280 ft.  
(60 m.p.h. = 88 ft. per sec.)

1 surveyor's chain = 22 yds.  
(1 engineer's chain = 100 ft.)  
1 link =  $\frac{1}{10}$  chain = 7.92 ins.  
(1 rod, pole, or perch =  $\frac{1}{4}$  chain.)  
1 furlong = 10 chains =  $\frac{1}{8}$  mile.

1 fathom = 6 ft. 1 cable = 100 fath.  
1 nautical mile = 6080 ft.  
= 1 minute of arc of equator.  
(1 knot = 1 nautical mile per hour.)

### Archaic (approximate) :

1 hand = 4 ins. 1 cubit = 18 ins.  
1 ell = 45 ins. 1 league = 3 miles.

### *Area*

1 acre = 10 sq. chains = 4840 sq. yds.  
1 sq. mile = 640 acres. (1 rood =  $\frac{1}{4}$  ac.)

### *Weight*

#### *Avoirdupois (General System)*

1 ounce (oz.) = 16 drams (dm.).  
1 pound (lb.) = 16 oz.  
1 stone = 14 lb. 1 quarter = 28 lb.  
1 hundredweight (cwt.) = 112 lb.  
= 4 quarters = 8 stones.  
1 ton = 20 cwt. = 2240 lb.

#### *Apothecary*

##### *(Drugs)*

1 drachm = 60 grs.  
(1 scruple = 20 grs.)

#### *Troy*

##### *(Precious Metals)*

1 pennyweight (dwt.) = 24 grs.

1 ounce = 20 dwt. = 8 drachms.

1 pound = 12 oz. = 5760 grs.

(1 lb. avoirdupois = 7000 grs.)

### *Money*

1 shilling (s.) = 12 pence (d.).

1 pound (£) = 20s.

Also farthing (1d.), florin (2s.), half-crown (2s. 6d.) and guinea (21s.).

### *Volume*

#### *(Liquid)*

1 gallon = 4 quarts = 8 pints  
= 32 gills = 16054 (1/6.2290) cu. ft.  
1 gallon water (62° F.) weighs 10 lb.  
av. (in air against brass weights).

1 fluid drachm (3) = 60 minims (M.).

1 fluid oz. (3) = 8 dr. =  $\frac{1}{20}$  pint.

1 fluid oz. water (62° F.) weighs 1 oz. av.

### *(Dry)*

1 peck = 2 gals. 1 bushel = 8 gals.

1 sack = 4 bush. 1 quarter = 8 bush.

(1 firkin = 9 gals. 1 barrel = 36 gals.)

1 register ton = 100 cu. ft.

1 rod = 1000 cu. ft.

## Weights and Measures of the United States of America

Weights and measures are the same as the English systems, except for small differences in standards, and the following exceptions :—

1 hundredweight (short) = 100 lb., and 1 ton (short) = 20 cwt. = 2000 lb. The English (long) ton, 2240 lb., is also used.

Dry measures of volume are 3 per cent. less than the corresponding English measures, being based on the Winchester bushel instead of the Imperial bushel. Fluid measures of volume are  $\frac{5}{6}$  of the corresponding English measures. (Hence in the U.S. system 1 bushel = 9.3092 fluid gallons.) Also 1 U.S. fluid ounce =  $\frac{1}{16}$  U.S. pint, so that a fluid ounce of water weighs 1.0408 oz. av. (See also conversion factors.)

A township = 36 sq. miles. A billion (French *Milliard*) =  $10^9$ , a trillion =  $10^{12}$ . (English billion =  $10^{12}$ , trillion =  $10^{24}$ .)

## *The Metric System*

The metre is (very nearly)  $10^{-7}$  of the distance from the pole to the equator.

The gram is (very nearly) the mass of 1 cubic cm. of water at maximum density (3.98° C.). (Actual mass of 1 c.c. of water = .999973 g.)

The litre is (very nearly) 1000 c.c. (1 litre = the volume of 1000 g. of water at 3.98° C. = 1000.027 c.c.)

Also 1 are = 100 sq. metres, so that 1 hectare = 10,000 sq. m. =  $\frac{1}{100}$  sq. km.; 1 metric quintal (doppel zentner) = 100 kg.; 1 metric ton = 1000 kg.; 1 Continental pound =  $\frac{1}{2}$  kg.; 1 stere = 1 cu. m. 1 micron ( $\mu$ ) =  $10^{-6}$  m. 1 angstrom unit (Å) =  $10^{-10}$  m.

Prefixes: micro-,  $10^{-6}$ ; mille-,  $10^{-3}$ ; centi-,  $10^{-2}$ ; deci-,  $10^{-1}$ ; Deka-, 10; Hecto-,  $10^2$ ; Kilo-,  $10^3$ ; Myria-,  $10^4$ ; Mega-,  $10^6$ .

### *Conversion Factors*

#### *Length*

1 inch = 2.5400 (1.39370) cm.  
1 foot = 30480 (1.32808) m.  
1 yard = 91440 (1.0936) m.  
1 mile = 1.6093 (1.62137) km.

#### *Capacity (U.S.A.)*

Fluid { 1 pint = 47317 (1.21134) lit.  
1 gall. = 3.7853 (1.26418) lit.  
Dry: 1 bush. = 35.238 (1.028378) lit.  
British pint, gallon, etc. = 1.20094 (1.83268) U.S. fluid pints, gallons, etc.  
British bushel, etc. = 1.03205 (1.96895) U.S. bushels, etc. (dry).
